- u If the patient is to be treated with a sclerosing agent, explain that the injected medication causes fibrosis, which fixes the rectum in place.
- u If surgery is to be performed, review the procedure and possible complications as needed. Make sure that the patient understands that surgery may not correct the prolapse and that it can cause fecal incontinence.
- u Teach the patient about prescribed medications, reviewing their desired and possible adverse effects.

INTRODUCTION

Cell metabolism is a complex progression of chemical changes that determines the final use of nutrients by the body. Cell metabolism has two main phases: catabolism and anabolism. In catabolism, the body breaks down complex substances into simple constituents for energy production or excretion. In anabolism, the tissue-building phase, simple substances combine to form more complex substances. This process produces new cellular material and stores energy. Both phases are accomplished by a chemical process that uses energy.

At the cellular level, metabolism provides energy in the form of adenosine triphosphate (ATP), a compound that is essential for cells to function. Three basic nutrients—carbohydrates, proteins, and fats—supply the energy needed for metabolism; vitamins and minerals also contribute to the process.

Basal metabolism refers to the energy that the resting body needs to maintain life. To maintain an activity level, a person needs energy above and beyond the basal metabolic rate. Activity levels are expressed as kilocalories used per minute. One kilocalorie (kcal) equals the amount of heat required to raise 1 kg of water 1° C at atmospheric pressure. This unit is used in the study of metabolism and to express the energy value of foods.

Activity levels are also expressed as metabolic equivalents (METs) of a task. A MET is the amount of oxygen used per kilogram of body weight per minute. One MET equals 3.5 cc oxygen/kg/minute. A person at rest expends approximately 1 MET.

Carbohydrate metabolism

Carbohydrates are composed of carbon, hydrogen, and oxygen. They provide the primary source of energy, yielding 4 kcal/g. Experts recommend that carbohydrates make up about 55% of a person's daily dietary intake.

Carbohydrates—ingested as starches (complex carbohydrates) and sugars (simple carbohydrates)—are the chief protein-sparing ingredients in a nutritionally sound diet. Carbohydrates are absorbed primarily as glucose; some are absorbed as fructose and galactose and converted to glucose by the liver. A body cell may metabolize glucose to produce the energy needed to maintain cell life or store it as glycogen.

Most of the energy produced by glucose metabolism goes toward forming the ATP in the cytoplasm and nucleoplasm of all body cells. ATP is the principal storage form of immediately available energy for cell reactions. Complex carbohydrates, such as rice, pasta, and legumes, provide more energy than simple carbohydrates, such as sugar, ice cream, and candy.

The liver synthesizes glycogen (glycogenesis) from glucose, then reconverts glycogen to glucose (glyco-genolysis) as needed. The liver can also transform excess glucose into fatty acids (lipogenesis) that may be stored as adipose tissue (fat).

A complex interplay of hormonal and neural controls regulates the homeostasis of glucose metabolism. Hormone secretions of five endocrine glands dominate the regulatory function:

- u *Beta cells of the islets of Langerhans* secrete the glucose-regulating hormone *insulin*, which decreases the blood glucose level by stimulating phosphorylase activity to accelerate liver glycogenolysis.
- u The *adrenal medulla*, as a physiologic response to stress, secretes *epinephrine*, which stimulates liver and muscle glycogenolysis to increase the blood glucose level.
- u *Corticotropin* and *glucocorticoids* also increase blood glucose levels. Glucocorticoids accelerate gluconeogenesis by promoting the flow of amino acids to the liver, where they are synthesized into glucose.
- u *Human growth hormone* limits the storage of fat and favors fat catabolism; consequently, it inhibits carbohydrate catabolism and thus raises blood glucose levels.
- u *Thyroid-stimulating hormone* and *thyroid hormone* have mixed effects on carbohydrate metabolism and may raise or lower blood glucose levels.

Protein metabolism

Proteins are complex organic compounds containing carbon, hydrogen, oxygen, and nitrogen atoms. They consist of amino acids joined by peptide bonds. One gram of protein yields 4 kcal. Proteins should make up about 15% of the daily caloric intake. The body needs protein for growth, maintenance, and repair of all tissue as well as for efficient performance of regulatory mechanisms.

Different proteins consist of different numbers and kinds of amino acids (organic compounds necessary for nitrogen balance but not synthesized in the body). Some amino acids are supplied by food (called essential amino acids), and the others can be produced by the body (called nonessential amino acids). Not all protein food sources are identical in quality. Complete proteins, such as those in poultry, fish, meat, eggs, milk, and cheese, can maintain body tissue and promote a normal growth rate. Incomplete proteins, such as vegetables and grains, lack essential amino acids.

The body must break down dietary protein into amino acids and peptides for absorption. Amino acids pass unchanged through the intestinal wall and travel by the portal vein through the liver and into the general circulation; from there, each tissue type absorbs the specific amino acid it needs to make its protein.

The collected amino acids derived from protein digestion, absorption, and endogenous tissue breakdown form a reserve metabolic pool, which ensures the availability

of a balanced mixture of amino acids to meet the energy needs of various organs and tissues.

The body doesn't store protein. This nutrient has a limited life span and constantly undergoes change (synthesis, degradation to amino acids, and resynthesis into new tissue proteins). The rate of protein turnover varies in different tissues. When the usual sources (available carbohydrate or fat) can't meet the energy demands of the body, the body uses protein precursors to generate energy.

In a healthy person, if caloric intake is adequate and protein intake exceeds the minimum requirement, nitrogen intake should equal nitrogen excretion, producing nitrogen balance. Positive nitrogen balance occurs when nitrogen intake exceeds output; for example, during pregnancy or growth periods. Negative nitrogen balance occurs when nitrogen output exceeds intake. Negative balance may result from inadequate dietary protein intake, which causes tissue to break down to supply energy; inadequate quality of ingested dietary protein; or excessive tissue breakdown after stress, injury, immobilization, or disease.

Fat metabolism

Like carbohydrates, fats consist of carbon, hydrogen, and oxygen. However, fats have a smaller proportion of oxygen than do carbohydrates and also differ in their structure and properties. The major fats are the glycerides (primarily triglycerides), phospholipids, and cholesterol. Glycerides, the end product of fat digestion, are used by body cells for energy. Phospholipids, formed by the liver, make up 95% of all blood lipids and serve several functions:

- ▮ assisting in the transport of fatty acids through the intestinal mucosa into the lymph
- ▮ providing protective insulation of nerve fibers as the myelin sheath
- ▮ participating in phosphate tissue reactions
- ▮ forming thromboplastin and some structural body elements.

Cholesterol—also formed by the liver—contributes to the formation of cholic acid, which produces the bile salts necessary for fat digestion. It also contributes to the synthesis of provitamin D, helps form hormones (especially the adrenocortical steroids and the steroid sex hormones), and helps produce the water-resistant quality of the skin. Together with phospholipids in the body cells, cholesterol helps form the insoluble cell membrane needed to maintain physical cellular integrity.

Fats are insoluble in water. However, when proteins combine with fats and phospholipids, the resulting lipoproteins can move through the aqueous medium of the blood. Lipoproteins contain proteins, triglycerides, cholesterol, phospholipids, and traces of related materials, including fat-soluble vitamins and steroid sex hormones. The percentage of protein determines the density of a lipoprotein. For example, a high-density lipoprotein contains a higher percentage of protein than does a low-density lipoprotein.

One gram of fat yields 9 kcal. Fats should make up about 30% of the daily caloric intake; that is 5% to 10% less than the amount ingested by the average American. Saturated fats should account for only about one-third of total fat consumption, and a person should consume no more than 300 mg of cholesterol per day. Fats are a major source of energy, and they give flavor to food. They have a high satiety value, reduce gastric motility, and remain in the stomach longer than other foods, thereby delaying the onset of hunger sensations.

Dietary fat carries fat-soluble vitamins. The absorption of vitamin A and its precursor, carotene, requires fat.

Fats not used for energy are synthesized into other lipids in the liver or stored as adipose tissue in subcutaneous tissue and in the abdominal cavity, where they insulate the body (reducing body heat loss in cold weather) and provide padding and protection for vital organs. When the body needs energy, adipose tissue releases fatty acids and glycerol into the circulation.

Role of vitamins and minerals

Vitamins and minerals are biologically active organic compounds that are essential for normal metabolism, growth, and development. They also contribute to enzyme reactions that facilitate the metabolism of amino acids, fats, and carbohydrates. A person requires relatively small amounts of vitamins, but inadequate vitamin intake leads to deficiency states or disorders. (For more information on vitamins, see the appendix “[Nutritional disorders](#).”)

Minerals are equally essential to good nutrition. They participate in various physiologic activities, including:

- ▮ metabolism of many enzymes
- ▮ membrane transfer of essential compounds
- ▮ maintenance of acid-base balance (stable concentration of hydrogen ions in the body) and osmotic pressure (pressure on a semipermeable membrane separating a solution from a solvent)
- ▮ nerve impulse transmission
- ▮ muscle contractility.

Minerals also contribute indirectly to the growth process. Although requirements for individual minerals vary, the greatest overall need occurs from birth to puberty.

Maintaining homeostasis

Fluid and electrolyte balance is an important aspect of metabolism. Water (the essential component of body fluids) and electrolytes serve many functions in the body. For instance, water helps regulate body temperature, transports nutrients and gases, conveys wastes to excretion sites, and helps maintain cell shape (through its high surface tension). Electrolytes (chemical compounds that dissociate in solution into charged particles called ions) carry an electric charge that conducts the electric current necessary for normal cell function.

Body fluids account for about 57% of total body weight in an average (154 lb [70 kg]) adult and about 75% in an average infant. Adipose tissue contains less water than any other tissue in the body, so obese people and women, who usually have a greater proportion of adipose tissue than men, have a lower percentage of body fluids.

Fluid balance

The term *fluid balance* describes fluid homeostasis: a total body water content that remains relatively constant. But fluid balance also means relatively constant fluid distribution between the body's main fluid compartments: intracellular fluid (ICF) and extracellular fluid (ECF).

Two-thirds of body fluid is ICF (contained within the cell); the other third is ECF (found outside the cells). The ECF is mainly found in two compartments: the vascular compartment (fluid in the blood vessels) and the interstitial compartment (fluid surrounding the cells). Small amounts of ECF are also found in dense connective tissue, bone, and transcellular spaces such as gut lumen, cerebrospinal fluid, and intraocular fluid. However, these aren't usually clinically significant.

For health and optimal growth and development, the patient must maintain both *external fluid balance* (steady-state fluid and electrolyte exchange between the body and the environment) and *internal fluid balance* (steady-state fluid and electrolyte exchange between fluid compartments). The body gains and loses water each day, with infants exchanging a greater amount than adults. To maintain body fluid, gains and losses must balance each other.

Regulation of fluids and electrolytes

Physical processes, such as diffusion, active transport, and osmotic pressure, affect the movement of solutes and water through both the ICF and the ECF compartments. Both compartments normally have equal concentrations of solutes (particles), so no *net* water movement occurs from one compartment to the other. Although water does move back and forth, each compartment's volume remains the same.

However, if one compartment's fluid concentration (osmolality) exceeds the other's, water moves between compartments by osmosis, creating a fluid imbalance. For

example, if extracellular water loss exceeds electrolyte loss (or if electrolyte gain exceeds water gain), ECF osmolality increases. The fluid contains more solutes per liter than normal and thus has a higher osmolality than the ICF. Because cell membranes don't allow free solute passage, water leaves cells and passes, by osmosis, into the ECF. Cell shrinkage and disrupted function result.

Conversely, if ECF gains more water than solutes (or loses more electrolytes than water), its osmolality declines and water moves from the ECF into the more concentrated ICF. (See [Comparing fluid tonicity.](#))

Internal regulation

Internal factors also alter fluid and electrolyte status. These factors and the regulating organs and hormones that maintain fluid and electrolyte balance are discussed here.

u *Stretch receptors in atrial walls.* These respond to increased fluid volume. The increased volume heightens sodium ion excretion, thereby increasing water excretion. It stimulates receptors that signal the brain to diminish sympathetic nervous system signals to the kidneys, thereby raising urine output. It also stimulates receptors that signal the posterior pituitary gland to inhibit secretions of antidiuretic hormone (ADH), causing the kidneys to increase urine output. It also increases arterial pressure and stimulates baroreceptors that increase the glomerular filtration rate, also causing greater urine output.

Comparing fluid tonicity

Isotonic fluid

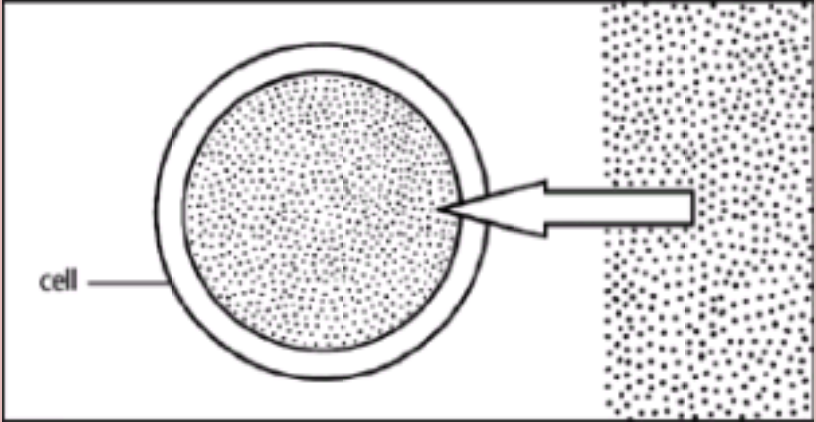

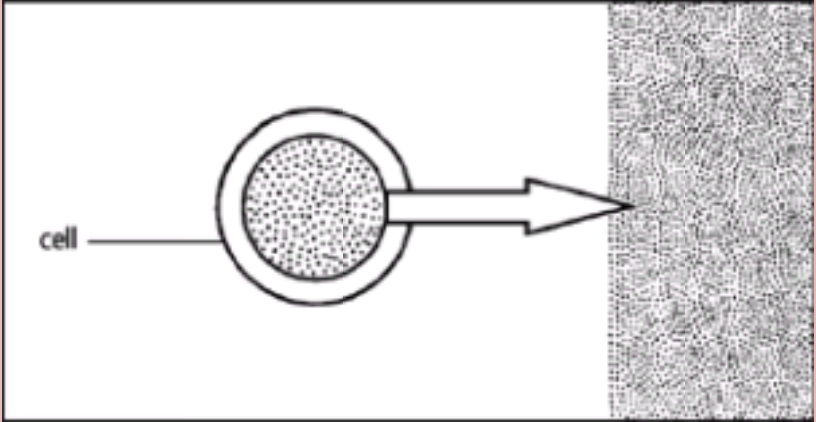

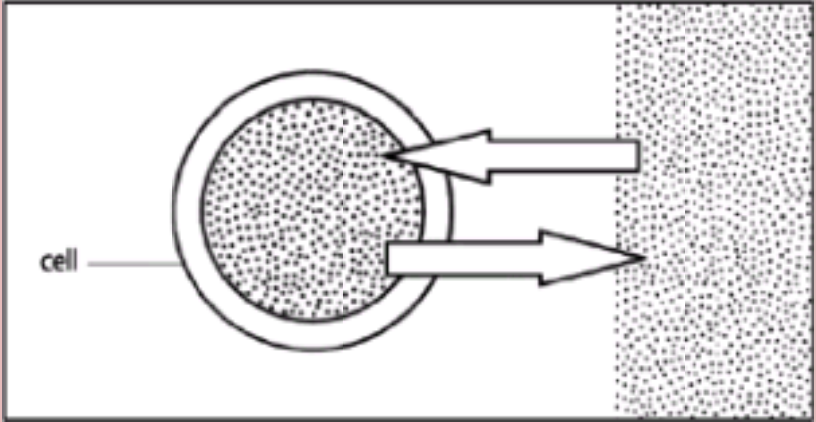

Isotonic fluid has a concentration of dissolved particles, or tonicity, equal to that of intracellular fluid (ICF). When isotonic fluids, such as dextrose 5% in water or normal saline solution, enter the circulation, they cause no net water movement across the semipermeable cell membrane. Because osmotic pressure is the same inside and outside the cells, the cells don't swell or shrink.

Hypertonic fluid

This type of fluid has a concentration greater than that of ICF. When you rapidly infuse a hypertonic solution, such as 3% sodium chloride or dextrose 50% in water, into a patient's body, water rushes out of the cells to the area of greater concentration and the cells shrivel. Dehydration can also make extracellular fluid (ECF) hypertonic, which also leads to cell shrinkage.

Hypotonic fluid

A hypotonic fluid has a concentration less than that of ICF. When you infuse a hypotonic solution, such as half-normal saline solution, into the body, water diffuses into the ICF, causing the cell to swell. Inappropriate use of I.V. fluids or severe electrolyte losses make body fluids hypotonic. For example, a patient with a sodium deficit after gastric suction may have hypotonic ECF.

- u *Osmoreceptors in the hypothalamus.* Hypothalamic osmoreceptors are stimulated by increased ECF osmolality, causing the posterior pituitary gland to secrete ADH.
- u *Pituitary gland.* The pituitary gland stores and releases ADH and corticotropin. ADH increases water reabsorption in the distal tubules and collecting ducts of the kidneys. Corticotropin influences production and release of adrenocortical hormones such as aldosterone.
- u *Kidneys.* The kidneys regulate fluid and electrolyte excretion and secretion. They also control ECF by regulating concentration of specific electrolytes, osmolality of body fluids, ECF volume, blood volume, and pH.
- u *Parathyroid glands.* These glands release parathyroid hormone, which regulates calcium. Diminished serum calcium levels spur parathyroid hormone secretion, causing increased calcium reabsorption in the kidneys.
- u *Lungs.* The lungs remove about 400 ml of water per day through exhalation. Lung abnormalities, such as hyperpnea, increase water loss. The lungs also play an important role in maintaining acid-base balance.
- u *Heart and blood vessels.* The heart pumps blood through the kidneys, creating enough pressure for urine to form. If this pumping action fails, renal perfusion and, consequently, fluid and electrolyte balance are affected.
- u *Adrenal glands.* By secreting aldosterone, the adrenal glands have an important effect on fluid and electrolyte balance. Increased aldosterone secretion enhances renal reabsorption of sodium and water and loss of potassium. Decreased aldosterone secretion reduces renal reabsorption of sodium and water and enhances potassium retention. Another adrenocortical hormone, cortisol, if secreted in large amounts, results in retention of sodium and water and loss of potassium.

Role of electrolytes

Six electrolytes play important roles in maintaining metabolic balance: *sodium, chloride, potassium, phosphate, calcium, and magnesium.*

Electrolytes dissociate in solution into electrically charged particles called ions. Because they conduct electric current, they permit cellular excitability. Ions can have a negative charge (anions) or a positive charge (cations). The composition of electrolytes in body fluids is electrically balanced so that the cations (sodium, potassium, calcium, and magnesium) equal the anions (chloride, bicarbonate, sulfate, phosphate, proteinate, and carbonic acid and other organic acids). Although these particles are present in relatively low concentrations, any deviation from normal levels can have profound physiologic effects.

Because cell membranes separate the ICF and ECF, the two compartments maintain very different ion concentrations. ICF contains large quantities of potassium and phosphates but very little sodium and chloride. ECF contains mostly sodium and chloride but very little potassium and phosphates.

Elevated electrolyte levels can result from either an electrolyte gain (from increased intake or decreased output) without a corresponding water gain, or from reduced body water (from excessive loss or diminished intake) without a corresponding electrolyte loss. Reduced electrolyte levels can occur from an electrolyte loss (from reduced intake or increased loss) without a corresponding water loss, or from increased body water without a corresponding electrolyte gain.

Acid-base balance

The body maintains the hydrogen ion concentration (pH) to keep the ECF pH between 7.35 and 7.45. This is accomplished primarily through the complex chemical regulation of carbonic acid by the lungs and of base bicarbonate by the kidneys. Maintaining the pH within the normal range is critical for the functioning of important physiologic processes.

Disturbances in acid-base balance can cause a lowered pH (acidosis) or an increased pH (alkalosis) and can produce serious and even lethal consequences. Such disturbances generally stem from:

- conditions that change the concentration of acids or bases at a rate that exceeds the body's normal homeostatic mechanisms
- abnormal conditions that impair the functioning of the body's homeostatic mechanisms
- nutritional deficiency or excess, disease, injury, or metabolic disturbance.

Assessing homeostasis

Results of laboratory tests supplement the information obtained from dietary history and physical examination, which offer gross clinical information about the quality, quantity, and efficiency of metabolic process. To support clinical information, anthropometry, height-weight ratio, and skin-fold thickness determinations are used to precisely define tissue nutritional status.

The following measures can help you maintain your patient's homeostasis:

- Obtain a complete dietary history and nutritional assessment to determine whether carbohydrate, fat, protein, vitamin, mineral, and water intake are adequate for energy production and for tissue repair and growth. Remember that during periods of rapid tissue synthesis (growth, pregnancy, healing), protein needs increase.
- Consult a dietitian about any patient who may be malnourished because of malabsorption syndromes, renal or hepatic disease, clear-liquid diets, or receiving nothing by mouth for more than 5 days. Planned meals that provide adequate carbohydrates, fats, and protein are necessary for convalescence. Supplementary carbohydrates are often needed to spare protein and achieve a positive nitrogen balance.
- Accurately record intake and output to assess fluid balance (this includes intake of oral liquids or I.V. solutions, and urine, gastric, and stool output).
- Weigh the patient daily, at the same time, with the same amount of clothing, and on the same scale. A weight loss of 2.3 lb (1 kg) is equivalent to the loss of 1 L of fluid.
- Observe the patient closely for insensible water or unmeasured fluid losses (such as through diaphoresis). Fluid loss from the skin and lungs (normally 900 ml/day) can reach as much as 2,000 ml/day from hyperventilation.

Laboratory tests for assessing nutritional status
<p>Blood and urine tests provide the most precise data about nutritional status, often revealing nutritional problems before they're clinically apparent. The list below explains some common tests and what their results mean.</p>
<p>Serum vitamins and minerals</p> <p>Vitamin and mineral deficiencies commonly screened for include A, B, B₁₂, folic acid, ascorbic acid, beta carotene, riboflavin and, sometimes, zinc, calcium, magnesium, iron, and other minerals.</p>
<p>Serum nutrients</p> <p>Glucose levels are used to assess suspected diabetes or hypoglycemia. Cholesterol and triglyceride levels are used to help differentiate the type of hyperlipoproteinemia.</p>
<p>Nitrogen balance</p> <p>A negative nitrogen balance indicates inadequate intake of protein or calories.</p>
<p>Hemoglobin and hematocrit</p> <p>Decreased levels can occur in protein-calorie malnutrition, iron deficiency, overhydration, hemorrhage, and hemolytic disease; elevated levels can occur in dehydration and polycythemia.</p>
<p>Serum albumin</p> <p>Reduced levels may indicate overhydration or visceral protein depletion because of GI disease, liver disease, or nephrotic syndrome. Elevated levels occur in dehydration.</p>
<p>Delayed hypersensitivity skin testing</p> <p>One or more positive responses in 24 to 48 hours to intradermally injected common recall antigens indicates intact cell-mediated immunity. Negative, delayed, or absent response may indicate protein-calorie malnutrition but may also be seen in patients on steroids or with cancer.</p>
<p>Creatinine-height index (CHI)</p> <p>This calculated value reflects muscle mass and estimates muscle protein depletion. Reduced CHI may indicated protein-calorie malnutrition or impaired renal function.</p>
<p>Serum prealbumin</p> <p>This carrier protein for thyroxine is a sensitive indicator of visceral protein.</p>
<p>Total lymphocyte count</p> <p>This provides an indication of immune status. Counts are low in malnutrition and acquired immunodeficiency syndrome.</p>

CULTURAL TIP Teach elderly patients—and others who are vulnerable to fluid imbalances—the importance of maintaining adequate fluid intake.

- Recognize I.V. solutions that are *hyposmolar*, such as half-normal saline solution. *Isosmolar* solutions include normal saline solution, 5% dextrose in 0.2% sodium chloride, lactated Ringer's solution, and 5% dextrose in water (which acts like a hypotonic solution because dextrose is quickly metabolized, leaving only free water). *Hyperosmolar* solutions include 5% dextrose in normal saline solution, 10% dextrose in water, and 5% dextrose in lactated Ringer's solution.
- When continuously administering hyposmolar solutions, watch for signs of water intoxication: head-aches, behavior changes (confusion or disorientation), nausea, vomiting, increasing blood pressure, and decreasing pulse rate.

- ⌞ When continuously administering hyperosmolar solutions, be alert for signs of hypovolemia: thirst, dry mucous membranes, slightly decreasing blood pressure, increasing pulse rate and respirations, low-grade fever (99° F [37.2° C]), and elevated hematocrit, hemoglobin, and blood urea nitrogen (BUN) levels.
- ⌞ Administer fluid cautiously, especially to the patient with cardiopulmonary or renal disease, and watch for signs of overhydration: constant and irritating cough, dyspnea, moist crackles, increasing central venous pressure, and pitting edema (a late sign). When the patient is in an upright position, neck and hand vein engorgement is a sign of fluid overload.

ALERT Many older patients take drugs for a variety of conditions. Drugs can affect the patient's nutritional status by altering nutrient absorption, metabolism, utilization, or excretion. Likewise, various foods, beverages, and mineral or vitamin supplements can affect the absorption and effectiveness of drugs. Be aware of these potential interactions when evaluating the patient's medication regimen and nutritional status.

The goal of metabolism and homeostasis is to maintain the complex environment of ECF (plasma), which nourishes and supports every body cell. Disturbances detectable by various laboratory determinations accurately reflect the state of metabolism, homeostasis, and nutrition throughout the body. These include measurements of albumin, prealbumin, and other blood proteins; electrolyte concentration; enzymes and antibody levels; and urine and blood chemistry levels (lipoproteins, glucose, BUN, and creatinine-height index). (See [Laboratory tests for assessing nutritional status.](#))

Metabolic anomalies

Some metabolic anomalies such as phenylketonuria are inherited; others such as hypoglycemia are acquired. Many can be treated with dietary changes.

GAUCHER'S DISEASE

Gaucher's disease, the most common lipidosis, causes an abnormal accumulation of glucocerebrosides in reticuloendothelial cells. It occurs in three forms: type I (adult), type II (infantile), and type III (juvenile). Type I may be diagnosed at any age and is 30 times more prevalent in people of Ashkenazic Jewish ancestry. Types II and III are less common and occur mainly in non-Jewish populations. Type II can be fatal within 9 months of onset, usually from pulmonary involvement.

Causes

Gaucher's disease results from an autosomal recessive inheritance, which causes decreased activity of the enzyme glucosylceramide b-glucosidase.

Complications

Possible complications of Gaucher's disease include neurologic impairment, portal hypertension, pathologic fractures, anemia and, in type II, respiratory failure.

Assessment findings

A patient with type I Gaucher's disease usually conveys visceral complaints; neurologic complaints are rare. Typically, the patient first notes an increasing left upper quadrant mass, followed by dull, aching joint pain and fever. He may report severe leg, arm, and back pain, occurring at adolescence. The patient may have a history of respiratory problems (pneumonia or cor pulmonale), pathologic fractures (particularly of the head and neck of the femur), and easy bruising and bleeding.

Inspection of an older patient may reveal a yellow pallor and brown-yellow pigmentation on the face and legs. On palpation, note splenomegaly, hepato-megaly and possible abdominal distention from large-bowel hypotonicity. Neurologic findings are normal. Fever may be present.

The history of a patient with type II disease emphasizes neurologic complaints with few visceral complaints. Problems usually become evident by age 3 months. Usually, the parent describes a weak cry, failure to thrive, and psychomotor retardation. Seizures and easy bruising and bleeding may also occur.

Inspection findings may include dysphagia and respiratory distress. On palpation, you may note abdominal distention. Neurologic assessment may reveal motor dysfunction and spasticity, occurring at age 6 to 7 months; strabismus; muscular hypertonicity; retroflexion of the head; neck rigidity, and hyperreflexia.

The history of a patient with type III disease includes both neurologic and visceral complaints, including any of the problems in types I and II disease. For example, the patient may report bone pain and easy bruising and bleeding. Palpation may disclose hepatosplenomegaly. Neurologic assessment may reveal poor coordination and mental ability, hypertonicity, strabismus, seizures, and myotonus. (See [Unexplained splenomegaly.](#))

Diagnostic tests

Bone marrow aspiration shows typical Gaucher's cells.

Direct assay of glucosylceramide b-glucosidase activity in blood, bone marrow, skin, or amniotic fluid samples shows absent or deficient activity, confirming the diagnosis.

Liver biopsy reveals increased glucosylceramide accumulation.

Supportive laboratory results include increased serum acid phosphatase level and decreased platelet count and serum iron level.

Magnetic resonance imaging is used to evaluate bone, liver, and spleen involvement.

Treatment

Therapy involves treating the underlying enzyme defect with alglucerase. This drug acts by replacing the missing enzyme in type I Gaucher's disease. Imiglucerase, produced by recombinant deoxyribonucleic acid technology, acts in much the same way. Supportive treatment consists of vitamins, supplemental iron or liver extract to prevent anemia caused by iron deficiency and to alleviate other hematologic problems, blood transfusions for anemia, splenectomy for hypersplenism, and analgesics for bone pain. Bone marrow transplantation may be performed in Gaucher's disease, but various studies of this treatment report a mortality ranging from 20% to 50%.

ADVANCED PRACTICE

Unexplained splenomegaly

Consider the possibility of Gaucher's disease in any patient with unexplained splenomegaly, especially if it's combined with increased serum acid phosphatase activity.

Nursing diagnoses

- ⌞ Altered parenting
- ⌞ Impaired gas exchange
- ⌞ Knowledge deficit
- ⌞ Pain
- ⌞ Risk for infection
- ⌞ Risk for injury

Key outcomes

- u The patient will express feelings of comfort.
- u Parents will participate in the care of the child.
- u The patient will maintain adequate ventilation.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will avoid complications.

Nursing interventions

- u For the patient confined to bed, prevent pathologic fractures by turning him carefully. If he's ambulatory, help him when he's getting out of bed or walking.
- u Observe closely for changes in pulmonary status. Plan the patient's activities within his level of tolerance. If he's on bed rest, have him turn, cough, and breathe deeply every 4 hours.
- u Maintain safety precautions (including the use of padded side rails if seizure activity is a possibility). Keep the patient's call button within easy reach and the bed lowered.
- u Observe for signs and symptoms of bleeding. Administer blood and blood products as ordered, and monitor for adverse reactions.
- u Maintain good hand washing, and implement standard precautions to protect the patient from infection.
- u Administer prescribed analgesics for pain. As indicated, use other pain-control techniques, including distraction, guided imagery, and meditation.
- u Help the patient and family develop effective coping mechanisms. Refer them to appropriate support services.
- u Recommend genetic counseling for parents who want to have another child.

Patient teaching

- u Explain all diagnostic tests and procedures to the patient or family.
- u Teach the patient and family supportive home care measures, including proper positioning, medication regimen, safety precautions, and nutrition guidelines. Also teach them to recognize and report status changes that require medical intervention.

GLYCOGEN STORAGE DISEASES

Glycogen storage diseases consist of at least 8, and possibly 12, distinct errors of metabolism. The diseases alter the synthesis or degradation of glycogen, the form in which glucose is stored in the body. All such metabolic errors are inherited.

Normally, muscle and hepatic cells store glycogen. Muscle glycogen is used in muscle contraction; liver glycogen can be converted into free glucose, which can then diffuse out of the hepatic cells to increase blood glucose levels.

Glycogen storage diseases manifest primarily as dysfunctions of the liver, heart, or musculoskeletal system. Signs and symptoms vary from mild and easily controlled hypoglycemia to severe organ involvement.

Causes

Almost all glycogen storage diseases (types I through V and type VII) are transmitted as autosomal recessive traits. The precise mode of transmission of type VI isn't known. Phosphorylase *b* kinase deficiency (type VIII) may be an X-linked recessive trait. (See [Types of glycogen storage disease](#).)

The most common type of glycogen storage disease is type I, glucose-6-phosphatase deficiency or von Gierke's disease, resulting from a deficiency of the liver enzyme glucose-6-phosphatase. This enzyme converts glucose-6-phosphatase into free glucose and is necessary for the release of stored glucagon and glucose in the bloodstream to relieve hypoglycemia.

Complications

Infants with glycogen storage disease may die of acidosis before age 2. If they survive past this age, with proper treatment, they may grow normally and live to adulthood with only minor hepatomegaly. Heat intolerance, easy bruising, slowed growth, incomplete sexual development, and hepatic adenomas are frequently seen by adolescence. Other complications include liver, heart, skeletal muscle, brain, and kidney involvement resulting in organ failure and death. Type II disease in particular can result in death from heart failure.

Types of glycogen storage disease		
TYPE	DEFICIENCY	INHERITANCE PATTERN
<i>I (von Gierke's)</i>	Glucose-6-phosphatase	Autosomal recessive
<i>II (Pompe's)</i>	Alpha-1, 4-glucosidase (acid maltase)	Probably autosomal recessive in most patients; late onset may be autosomal dominant
<i>III (Cori's)</i>	Debranching enzyme (amylo-1,6-glucosidase)	Autosomal recessive
<i>IV (Andersen's)</i>	Branching enzyme (amylo-1,4-1,6-transglucosidase)	Autosomal recessive
<i>V (McArdle's)</i>	Muscle phosphorylase	Autosomal recessive
<i>VI (Hers')</i>	Possible hepatic phosphorylase	Probably autosomal recessive
<i>VII</i>	Muscle phosphofructokinase	Probably autosomal recessive (rare)
<i>VIII</i>	Hepatic phosphorylase kinase	X-linked and autosomal recessive forms

Assessment findings

Typically, the history of a patient with liver glycogen storage disease (types I, III, IV, VI, and VII) reveals rapid onset of hypoglycemia and acidosis when food is withheld. Palpation reveals hepatomegaly.

In a patient with type I disease, the history may also disclose symptomatic hypoglycemia and lactic acidosis, usually occurring during the first 12 months of life. Symptoms of muscle glycogen storage disease (types II, V, and VII) include poor muscle tone, hyperlipidemia, GI bleeding, and coma. Children may present with low resistance to infection and, without proper treatment, short stature. Adolescents may have gouty arthritis and nephropathy, chronic tophaceous gout, bleeding

(especially epistaxis), small superficial vessels visible in the skin due to impaired platelet function, and fat deposits in the cheeks, buttocks, and subcutaneous tissues.

Inspection of a patient with type I disease may reveal a protuberant abdomen due to an enlarged liver, thin extremities, small superficial vessels visible in the skin due to impaired platelet function, full cheeks, round face, short stature, and xanthomas over extensor surfaces of the arms and legs due to hyperlipidemia. Ophthalmoscopic examination may demonstrate bilateral, yellow lesions in the fundi. Palpation may disclose hepatomegaly and, possibly, kidney enlargement. Motor system assessment may indicate poor muscle tone. Other symptoms include steatorrhea and osteoporosis, probably secondary to negative calcium balance. Proper treatment of glycogen storage disease should prevent this effect.

A patient with muscle glycogen storage disease (types V and VII) may report the onset of pain and muscle cramps during and after strenuous exercise. Physical assessment often discloses marked hypotonia.

Patients with glycogen storage disease with individualized pathophysiology (types II and IV) may have a history of failure to thrive and motor weakness. Physical assessment findings vary according to the disease type and patient's age. For example, in patients with type II disease, auscultation may reveal signs of heart failure in infancy. In patients with type IV disease, palpation may reveal hepatomegaly.

Diagnostic tests

Liver biopsy is used to confirm diagnosis of type IA disease by showing normal glycogen synthetase and phosphorylase enzyme activities but reduced or absent glucose-6-phosphatase activity. Glycogen structure is normal, but amounts are elevated.

Laboratory studies of plasma demonstrate low glucose levels but high levels of free fatty acids, triglycerides, cholesterol, and uric acid in type IA disease. Serum analysis reveals elevated pyruvic acid levels and elevated lactic acid levels. Prenatal diagnoses are available for types II, III, and IV.

Injection of glucagon or epinephrine increases pyruvic and lactic acid levels but doesn't increase blood glucose levels in patients with type IA disease. A glucose tolerance test curve typically shows depletion hypoglycemia and reduced insulin output.

Treatment

For patients with type I glycogen storage disease, the goals of treatment include maintaining glucose homeostasis and preventing secondary consequences of hypoglycemia through frequent feedings and constant nocturnal nasogastric (NG) tube feedings. Dietary treatment calls for a regimen of about 60% carbohydrate intake, with low fat and normal amounts of protein and calories; carbohydrates should contain glucose or glucose polymers only, such as raw cornstarch.

Therapy for type III disease includes frequent feedings and a high-protein diet. Type IV disease necessitates a high-protein, high-calorie diet, bed rest, diuretics, sodium restriction, and paracentesis, necessary to relieve ascites.

Patients with types V and VII diseases require no treatment except avoidance of strenuous exercise. No treatment may be necessary for types IV and VIII diseases.

There is no effective treatment for type II glycogen storage disease.

Nursing diagnoses

- u Activity intolerance
- u Body image disturbance
- u Decreased cardiac output
- u Fluid volume deficit
- u Knowledge deficit
- u Risk for infection

Key outcomes

- u The patient won't develop complications.
- u The patient's vital signs will remain stable.
- u The patient's intake will equal his output.
- u The patient will perform activities of daily living within the confines of the disease process.
- u The patient and family members will express an understanding of the disease and treatment regimen.

Nursing interventions

For type I disease:

- u Watch for and report signs of infection (fever, chills, myalgia, purulent drainage) and of hepatic encephalopathy (mental confusion, stupor, asterixis, coma) due to increased blood ammonia levels. Also monitor for hypoglycemia and lactic acidosis.
- u As warranted, plan care to provide sufficient rest periods balanced with tolerated activity. Provide safety measures for the patient with muscle weakness.
- u Help the patient and family members obtain psychosocial support, as needed, to deal with the poor prognosis, body image disturbances, and lifestyle adaptations.

For other types:

- u Type II: Explain test procedures, such as electromyography and EEG, thoroughly.
- u Type III: Instruct the patient to eat a high-protein diet (eggs, nuts, fish, meat, poultry and cheese).
- u Type IV: Watch for signs of hepatic failure (nausea, vomiting, irregular bowel function, clay-colored stools, right upper quadrant pain, jaundice, dehydration, electrolyte imbalance, edema, and changes in mental status progressing to coma).

When caring for patients with type II, III, or IV glycogen storage disease, offer the parents reassurance and emotional support. Recommend and arrange for genetic counseling, if appropriate.

- u Types V through VII: Care for these patients is minimal. Explain the disorder to the patient and family members, and help them accept the limitations imposed by the patient's particular type of glycogen storage disease.

Patient teaching

- u Before discharge, teach the patient with type I disease and his family members about dietary treatment, especially the need for carbohydrates containing mainly starch. Teach them to sweeten foods with glucose only.
- u Instruct the patient and family members how to insert an NG tube, use a pump with alarm capacity, monitor blood glucose, and recognize and report symptoms of hypoglycemia, including fatigue, headache, hunger, malaise, and a rapid heart rate.
- u Teach the patient and family members to recognize and report signs of infection, including fever and chills, malaise, myalgia, and purulent drainage.
- u Explain test procedures, which may include liver or muscle biopsy, electromyography, or EEG.
- u Inform the patient with type III or VI disease (if warranted) about the need for frequent feedings. Tell him to ingest adequate calories (mainly from carbohydrates) and protein (eggs, nuts, fish, meat, poultry, and cheese).
- u Advise the patient with type V or VII disease to avoid strenuous exercise. Help him to accept the physical limitations imposed by his disease.

HYPERLIPOPROTEINEMIA

Hyperlipoproteinemia—marked by increased plasma concentrations of one or more lipoproteins—affects lipid transport in serum. Primary hyperlipoproteinemia includes at least five distinct metabolic disorders, all of which may be inherited. Hyperlipoproteinemia also occurs secondary to other conditions such as diabetes

mellitus.

The disorder produces various clinical changes, from relatively mild symptoms that can be corrected by dietary management to potentially fatal pancreatitis. (See [Types of hyperlipoproteinemia](#).)

Causes

The primary hyperlipoproteinemias result from genetic disorders. Types I and III are transmitted as autosomal recessive traits; types II, IV, and V are transmitted as autosomal dominant traits. Secondary hyperlipoproteinemia results from another metabolic disorder, such as diabetes mellitus, pancreatitis, hypothyroidism, or renal disease.

Complications

Sequelae of hyperlipoproteinemia include coronary artery disease and pancreatitis.

Assessment findings

The history of a patient with type I disease typically reveals recurrent attacks of severe abdominal pain similar to pancreatitis, usually preceded by fat intake. The patient may also report malaise and anorexia.

Inspection may reveal papular or eruptive xanthomas (pinkish yellow cutaneous deposits of fat) over pressure points and extensor surfaces. Ophthalmoscopic examination typically reveals lipemia retinalis (reddish white retinal vessels). Palpation may disclose abdominal spasm, rigidity, or rebound tenderness, and hepatosplenomegaly, with liver or spleen tenderness. Fever may be present.

A patient with type II disease may have a history of premature and accelerated coronary atherosclerosis, with symptoms typically developing when the patient is in his 20s or 30s. Inspection commonly reveals tendinous xanthomas (firm masses) on the Achilles tendons and tendons of the hands and feet, tuberous xanthomas, xanthelasma, and juvenile corneal arcus (opaque ring surrounding the corneal periphery).

Typically, a patient with type III disease doesn't complain of clinical symptoms until after age 20, when severe atherosclerosis may develop. The patient's history may include such aggravating factors as obesity, hypothyroidism, and diabetes mellitus.

Inspection may reveal tuberoeruptive xanthomas (soft, inflamed, pedunculated lesions) over the elbows and knees and palmar xanthomas on the hands, particularly the fingertips (orange or yellow discolorations of the palmar and digital creases).

A patient with type IV disease may have a history of atherosclerosis and early coronary artery disease. Patient history may also include excessive alcohol consumption, poorly controlled diabetes mellitus, and ingestion of birth control pills containing estrogen. These factors can precipitate severe hypertriglyceridemia. Hypertension and hyperuricemia may also be present. Inspection commonly reveals obesity. Although not characteristic, xanthomas may be noted during exacerbations.

The history of a patient with type V disease may reveal abdominal pain associated with pancreatitis and complaints related to peripheral neuropathy. Inspection may reveal eruptive xanthomas on the extensor surface of the arms and legs. Ophthalmoscopic examination may reveal lipemia retinalis. Palpation may disclose hepatosplenomegaly.

Diagnostic tests

Serum lipid profiles—elevated levels of total cholesterol, triglycerides, very-low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), or high-density lipoproteins (HDLs)—indicate hyperlipoproteinemia.

Treatment

Primary treatment is focused on dietary management, including weight reduction, restriction of cholesterol and saturated animal fat intake, and inclusion of polyunsaturated vegetable oils, which reduce concentration of plasma LDL. Dietary fat should account for no more than 30% of the total caloric intake.

The second therapeutic aim is to eliminate aggravating factors, such as diabetes mellitus, alcoholism, and hypothyroidism. The patient should also reduce other risk factors that may predispose him to atherosclerosis. Self-care measures may include cessation of smoking, treatment of hypertension, maintenance of a good exercise and physical fitness program and, if the patient has diabetes mellitus, control of blood glucose levels.

Treatment may be supplemented by drug therapy (cholestyramine, clofibrate, colestipol hydrochloride, gemfibrozil, lovastatin, nicotinic acid, pravastatin sodium, probucol, or simvastatin) to lower plasma concentrations of lipoproteins, either by decreasing their production or by increasing their removal from plasma.

ADVANCED PRACTICE

Types of hyperlipoproteinemia

The following chart compares the five forms of hyperlipoproteinemia, their causes and incidence, and diagnostic findings.		
TYPE	CAUSES AND INCIDENCE	DIAGNOSTIC FINDINGS
Type I (Frederickson's hyperlipoproteinemia, fat-induced hyperlipidemia, idiopathic familial)	<ul style="list-style-type: none"> Deficient or abnormal lipoprotein lipase, resulting in decreased or absent lipolytic activity after heparin administration Relatively rare Present at birth 	<ul style="list-style-type: none"> Chylomicrons (very-low-density lipoprotein [VLDL], low-density lipoprotein [LDL], highdensity lipoprotein [HDL]) in plasma 14 hours or more after last meal High elevated serum chylomicron and triglyceride levels; slightly elevated serum cholesterol levels Decreased serum lipoprotein lipase levels Leukocytosis
Type II (familial hyperbetalipoproteinemia, essential familial hypercholesterolemia)	<ul style="list-style-type: none"> Deficient cell surface receptor that regulates LDL degradation and cholesterol synthesis, resulting in increased levels of plasma LDL over joints and pressure points Onset between ages 10 and 30 	<ul style="list-style-type: none"> Increased plasma concentrations of LDL Elevated serum LDL and cholesterol levels Increased LDL levels detected by amniocentesis
Type III (familial broad-beta disease, xanthoma tuberosum)	<ul style="list-style-type: none"> Primary defect involving deficient LDL receptor Uncommon: usually occurring after age 20, possibly earlier in men 	<ul style="list-style-type: none"> Abnormal serum beta-lipoprotein levels Elevated cholesterol and triglyceride levels Slightly elevated glucose tolerance
Type IV (endogenous, hypertriglyceridemia, hyperbetalipoproteinemia)	<ul style="list-style-type: none"> Primary defect unknown; usually occurs with increased prevalence of obesity, diabetes, and hypertension Relatively common, especially in middle-aged men 	<ul style="list-style-type: none"> Elevated VLDL levels Moderately increased plasma triglyceride levels Normal or slightly elevated serum cholesterol levels Mildly abnormal glucose tolerance Family history Early coronary artery disease
Type V (mixed hypertriglyceridemia, mixed hyperlipidemia)	<ul style="list-style-type: none"> Defective triglyceride clearance causes pancreatitis; usually secondary to another disorder, such as obesity and nephrosis Uncommon: usually occurring in late adolescence or early adulthood 	<ul style="list-style-type: none"> Chylomicrons in plasma Elevated plasma VLDL levels Elevated serum cholesterol and triglyceride levels

Type I hyperlipoproteinemia requires long-term weight reduction, with fat intake restricted to less than 20 g/day. A 20- to 40-g/day, medium-chain triglyceride diet may be ordered to supplement caloric intake. The patient should also avoid alcoholic beverages to decrease plasma triglyceride levels. The prognosis is good with treatment; without treatment, death can result from pancreatitis.

For type II hyperlipoproteinemia, dietary management to restore normal lipid levels and decrease the risk of atherosclerosis includes restriction of cholesterol intake to less than 300 mg/day for adults and less than 150 mg/day for children. Additional measures include restricting triglyceride intake to less than 100 mg/day for children and adults. The diet should be high in polyunsaturated fats.

In famialial hypercholesterolemia, nicotinic acid with a bile acid usually normalizes LDL levels.

If the patient can't tolerate drug therapy, surgical creation of an ileal bypass may be necessary. This surgery accelerates the loss of bile acids in the stool and often causes heterozygotes to show a moderate to marked reduction of plasma cholesterol levels.

For severely affected homozygote children, portacaval shunt may be used as a last resort to reduce plasma cholesterol levels. Prognosis remains poor regardless of treatment in homozygotes; myocardial infarction usually causes death before age 30.

For type III hyperlipoproteinemia, dietary management includes restriction of cholesterol intake to less than 300 mg/day; carbohydrates must also be restricted, and polyunsaturated fats are increased. Clofibrate and niacin help lower blood lipid levels. Weight reduction is helpful. With strict adherence to the prescribed diet, the prognosis is good.

For type IV hyperlipoproteinemia, weight reduction may normalize blood lipid levels without additional treatment. Long-term dietary management includes restricted cholesterol intake, increased polyunsaturated fats, and avoidance of alcoholic beverages. Some patients respond to drug therapy; for example, gemfibrozil or nicotinic acid. Clofibrate and niacin may be helpful in treating certain patients. The prognosis remains uncertain, however, because of predisposition to premature coronary artery disease (CAD).

The most effective treatment for type V hyperlipoproteinemia is weight reduction and long-term maintenance of a low-fat diet. Alcoholic beverages and oral contraceptives must be avoided. Niacin, clofibrate, gemfibrozil, and a 20- to 40-g/day medium-chain triglyceride diet may be helpful. The prognosis is uncertain because of the risk of pancreatitis. Increased fat intake can cause recurrent bouts of illness, possibly leading to pseudocyst formation, hemorrhage, and death.

Nursing diagnoses

u Altered tissue perfusion (cardiopulmonary)
 u Anxiety
 u Fear
 u Knowledge deficit
 u Risk for injury

Key outcomes

u The patient won't develop complications.
 u The patient's vital signs will remain stable.
 u The patient and family members will express an understanding of the disorder and treatment regimen.
 u The patient won't injure himself.

Nursing interventions

- u Administer antilipemics as ordered, taking measures to prevent or minimize adverse reactions. Monitor the patient for reactions, and document and report any that occur.
- u Urge the patient to adhere to his diet (usually 1,000 to 1,500 calories/day), avoid excess sugar and alcoholic beverages, minimize the intake of saturated fats (higher in meats and coconut oil), and increase the intake of polyunsaturated fats (vegetable oils).
- u Assist the patient with additional lifestyle changes. Stress the need for medically supervised exercise and cessation of smoking. Refer him to safe, effective programs and support groups as needed.
- u Assess the patient for signs and symptoms related to CAD or its sequelae.
- u Encourage the patient to verbalize his fears related to premature CAD. Offer support and provide a clear explanation of the treatment regimen. Refer the patient for additional counseling, if needed.

Patient teaching

- u For the 2 weeks preceding serum cholesterol and serum triglyceride tests, instruct the patient to maintain a steady weight and to adhere strictly to the prescribed diet. He should fast for 12 hours before the test.
- u Caution women with elevated serum lipids to avoid oral contraceptives or drugs that contain estrogen.
- u Provide the patient with written information about foods high in cholesterol and saturated fats. Refer him to a dietitian, if necessary
- u Teach the patient about the varying components of the lipid profile and the ramifications of each. Discuss various means of lowering VLDL and LDL levels while increasing HDL levels.
- u Make sure the patient understands his prescribed medication regimen. Provide verbal and written information on drug name, action, dosage, adverse reactions, monitoring requirements, and signs and symptoms requiring medical evaluation.

HYPOGLYCEMIA

Hypoglycemia is a potentially dangerous, abnormally low blood glucose level. It occurs when glucose burns up too rapidly, when the glucose release rate falls behind tissue demands, or when excessive insulin enters the bloodstream. When the brain is deprived of glucose, as with oxygen deprivation, its functioning becomes deranged. With prolonged glucose deprivation, tissue damage—or even death—may occur.

Hypoglycemia may be classified as reactive or fasting. Reactive hypoglycemia results from the body's reaction to digestion or from the administration of excessive insulin.

Fasting hypoglycemia causes discomfort during periods of abstinence from food. Blood glucose levels decrease gradually. This rare type of hypoglycemia occurs most commonly in the early morning before breakfast.

Manifestations of hypoglycemia tend to be vague and depend on how quickly the patient's glucose levels drop. Gradual onset of hypoglycemia produces predominantly central nervous system (CNS) signs and symptoms; a more rapid decline in plasma glucose levels results predominantly in adrenergic signs and symptoms. (See [Understanding acute hypoglycemia.](#))

Causes and pathophysiology

The two forms of hypoglycemia have different causes and occur in different types of patients.

Reactive hypoglycemia

Several forms of reactive hypoglycemia occur. In a diabetic patient, it may result from administration of too much insulin or—less commonly—too much oral antidiabetic medication. In a mildly diabetic patient (or one in the early stages of diabetes mellitus), reactive hypoglycemia may result from delayed and excessive insulin production after carbohydrate ingestion.

Similarly, a nondiabetic patient may suffer reactive hypoglycemia from a sharp increase in insulin output after a meal. Sometimes called postprandial hypoglycemia, this type of reactive hypoglycemia usually disappears when the patient eats something sweet.

In some patients, reactive hypoglycemia has no known cause (idiopathic reactive) or may result from total parenteral nutrition for gastric dumping syndrome or from impaired glucose tolerance.

Fasting hypoglycemia

Fasting hypoglycemia usually results from an excess of insulin or insulin-like substance or from a decrease in counterregulatory hormones. It can be exogenous, resulting from external factors, such as alcohol and drug ingestion, or endogenous, resulting from organic problems.

Endogenous hypoglycemia may result from tumors or liver disease. Insulinomas—small islet cell tumors in the pancreas—secrete excessive amounts of insulin, which inhibits hepatic glucose production. The tumors are benign in 90% of patients.

Extrapancreatic tumors, although uncommon, can also cause hypoglycemia by increasing glucose utilization and inhibiting glucose output. Such tumors occur primarily in the mesenchyma, liver, adrenal cortex, GI system, and lymphatic system. They may be benign or malignant.

Among nonendocrine causes of fasting hypoglycemia are severe liver diseases, including hepatitis, cancer, cirrhosis, and liver congestion associated with heart failure. All these conditions reduce the uptake and release of glycogen from the liver.

Some endocrine causes include destruction of pancreatic islet cells; adrenocortical insufficiency, which contributes to hypoglycemia by reducing the production of cortisol and cortisone needed for gluconeogenesis; and pituitary insufficiency, which reduces corticotropin and growth hormone levels.

Causes in infants and children

Hypoglycemia is at least as common in neonates and children as it is in adults. Usually, infants develop hypoglycemia because of the increased number of cells per unit of body weight and because of increased demands on stored liver glycogen to support respirations, thermoregulation, and muscle activity.

In full-term neonates, hypoglycemia may occur 24 to 72 hours after birth and is usually transient. In infants who are premature or small for gestational age, onset of hypoglycemia is much more rapid—it can occur as soon as 6 hours after birth—due to the infants' small, immature livers, which produce much less glycogen. A rare cause of hypoglycemia in infants is nesidioblastosis, a benign condition of the insulin-producing islet cells. The treatment is surgical.

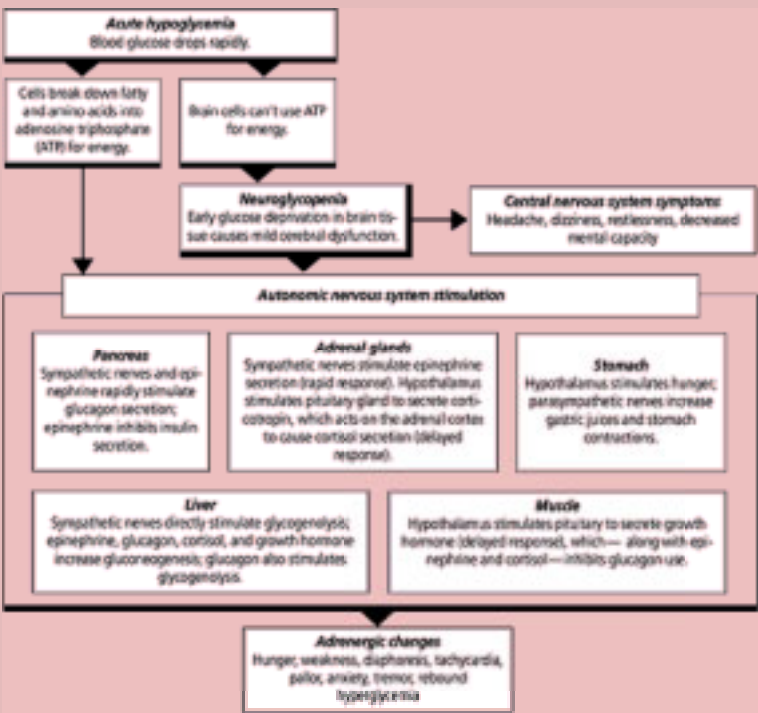

PATHOPHYSIOLOGY

Understanding acute hypoglycemia

Normally, homeostatic mechanisms maintain blood glucose levels within narrow limits (60 to 120 mg/dl). The body burns available glucose and stores the rest as glycogen in the liver and muscles. When the glucose level drops, the liver converts glycogen back to glucose (glycogenolysis) or makes new glucose from noncarbohydrate sources, such as amino acids and fatty acids (gluconeogenesis).

Hormones maintain the delicate balance between glucose production and use. This balance is upset when a patient has hypoglycemia. The flowchart below shows the events that lead to central and autonomic nervous system reactions associated with hypoglycemia.

Maternal disorders that can produce hypoglycemia in infants within 24 hours after birth include diabetes mellitus, pregnancy-induced hypertension, erythroblastosis, and glycogen storage disease.

Complications

Prolonged or severe hypoglycemia (blood glucose levels 20 mg/dl or less) can cause permanent brain damage and may be fatal.

Assessment findings

The history of a patient with suspected hypoglycemia should include the pattern of food intake for the preceding 24 hours as well as drug and alcohol use. The medical or surgical history may disclose the existence of causative factors, such as gastrectomy and hepatic disease.

A patient with reactive hypoglycemia may report adrenergic symptoms, such as diaphoresis, anxiety, hunger, nervousness, and weakness, indicating a rapid decline in blood glucose levels. A patient with fasting hypoglycemia may report signs and symptoms of CNS disturbance, such as dizziness, headache, clouding of vision, restlessness, and mental status changes, indicating a slow decline in blood glucose levels. With prolonged glucose deprivation, the patient's history (obtained from family or friends, if necessary) may reveal seizures, decreasing level of consciousness (LOC), and coma. A patient with pharmacologic hypoglycemia may experience a rapid or slow decline in blood glucose levels.

Inspection may reveal adrenergic signs, such as diaphoresis, pallor, and tremor; or CNS signs, such as restlessness, loss of fine-motor skills, and altered LOC. Palpation may disclose tachycardia.

ASSESSMENT TIP Infants and children with hypoglycemia generally exhibit vague symptoms, such as refusal to feed and a weak or high-pitched cry. Inspection may reveal tremor, twitching, sweating, limpness, seizures, and coma.

Diagnostic tests

Glucometer readings provide quick screening methods for determining blood glucose levels.

Laboratory testing confirms the diagnosis by showing decreased blood glucose values. The following values indicate hypoglycemia:

- u full-term neonates—less than 30 mg/dl before feeding, less than 40 mg/dl after feeding
- u preterm neonates—less than 20 mg/dl before feeding, less than 30 mg/dl after feeding
- u children and adults—less than 40 mg/dl before a meal, less than 50 mg/dl after a meal.

In addition, a 5-hour glucose tolerance test may be administered to provoke reactive hypoglycemia. Following a 12-hour fast, laboratory testing to detect plasma insulin and plasma glucose levels may identify fasting hypoglycemia.

A C-peptide assay is used to help diagnose fasting hypoglycemia. It also differentiates fasting hypoglycemia caused by an insulinoma from fasting hypoglycemia caused by insulin injections.

Treatment

Reactive hypoglycemia requires dietary modification to help delay glucose absorption and gastric emptying. Usually, this includes small, frequent meals; avoidance of simple carbohydrates (including alcohol and fruit drinks); and ingestion of complex carbohydrates, fiber, and fat. The patient may also receive anticholinergic drugs to slow gastric emptying and intestinal motility and to inhibit vagal stimulation of insulin release.

For fasting hypoglycemia, surgery and drug therapy may be required. In patients with insulinoma, removal of the tumor is the treatment of choice. Drug therapy may include nondiuretic thiazides such as diazoxide to inhibit insulin secretion; streptozocin and hormones, such as glucocorticoids; and long-lasting glycogen.

For infants who have hypoglycemia or are at risk for developing it, therapy includes preventive measures. A hypertonic solution of dextrose 10% in water, calculated at 5 to 10 ml/kg of body weight, administered I.V. over 10 minutes and followed by 4 to 8 mg/kg/minute for maintenance should correct a severe hypoglycemic state in neonates. To reduce the chance of hypoglycemia in high-risk infants, feed-ings—of either breast milk or a solution of dextrose 5% to 10% in water—should begin as soon after birth as possible.

ALERT For severe hypoglycemia (producing confusion or coma), initial treatment is usually I.V. administration of a bolus of 25 or 50 g of glucose as a 50% solution. This is followed by a constant infusion of glucose until the patient can eat a meal. A patient who experiences adrenergic reactions without CNS symptoms may receive oral carbohydrates (parenteral therapy isn't required).

Nursing diagnoses

- u Altered tissue perfusion (cerebral)
- u Anxiety
- u Knowledge deficit
- u Noncompliance
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient won't develop complications.
- u The patient won't incur injury.
- u The patient's vital signs will remain stable.
- u The patient and family members will express an understanding of the illness and treatment modalities.
- u The patient will remain alert and oriented to environment without decreasing LOC.

Nursing interventions

- u Watch for and report signs of hypoglycemia in high-risk patients.
- u Implement measures to protect the unconscious patient such as maintaining a patent airway.
- u Monitor infusion of hypertonic glucose (especially in the neonate) to avoid hyperglycemia, circulatory overload, and cellular dehydration.
- u Measure blood glucose levels as ordered.
- u Monitor the effects of drug therapy, and watch for the development of any adverse reactions.

Patient teaching

- u Explain the purpose, preparation, and procedure for any diagnostic tests.
- u Emphasize the importance of carefully following the prescribed diet to prevent a rapid drop in blood glucose levels. Advise the patient to eat small meals throughout the day, and mention that bedtime snacks may be necessary to keep blood glucose at an even level. Instruct the patient to avoid alcohol and caffeine because they may trigger severe hypoglycemic episodes. (See [Treating hypoglycemia at home.](#))
- u If the patient is obese and has impaired glucose tolerance, suggest ways he can restrict his caloric intake and lose weight. If necessary, help him find a weight-loss support group.
- u Warn the patient with fasting hypoglycemia not to postpone or skip meals and snacks. Instruct the patient to call his doctor for instructions if he doesn't feel well enough to eat.
- u Discuss lifestyle and personal habits to help the patient identify precipitating factors, such as poor diet, stress, or noncompliance with diabetes mellitus treatment. Explain ways that he can change or avoid each precipitating factor. If necessary, teach him stressreduction techniques, and encourage him to join a support group.

HOME CARE

Treating hypoglycemia at home

In your teaching, emphasize the importance of preventing or promptly treating hypoglycemic episodes to avoid severe complications.

Make sure the patient understands the key danger with hypoglycemia: When it occurs, he may quickly lose his ability to think clearly. If this happens while he's driving a car or operating machinery, a serious accident could result.

Inform the patient that he should note what early symptoms he typically experiences with hypoglycemia. Family, friends, and coworkers should also be able to recognize the warning signs so that immediate treatment can be initiated.

Review with the patient and family the treatment measures they should follow if the patient has a hypoglycemic episode. If the patient is conscious, he should consume a readily available source of glucose, such as five to six pieces of hard candy; 4 to 6 oz of apple juice, orange juice, cola, or other soft drink; or 1 tablespoon of honey or grape jelly.

If the patient is unconscious, he should be given a subcutaneous injection of glucagon. Teach members of the patient's family how to administer glucagon. Advise the patient and family members to notify the doctor if hypoglycemic episodes don't respond to treatment, or if they occur frequently.

- u Teach the patient about precautions to take when exercising; for example, tell him to consume extra calories and not to exercise alone or when his blood glucose level is likely to drop.
- u Inform the patient that he should carry a source of fast-acting carbohydrates such as hard candy with him at all times. Advise him to wear a medical identification bracelet or to carry a medical identification card that describes his condition and its emergency treatment measures.
- u For the patient with pharmacologic hypoglycemia from insulin or oral antidiabetic agents, review the essentials of managing diabetes mellitus, if indicated.
- u If warranted, teach the patient about prescribed drug therapy or surgery.
- u Because hypoglycemia is a chronic disorder, encourage the patient to see his doctor regularly.
- u Encourage the patient and family to discuss their concerns about the patient's condition and treatment.

LACTOSE INTOLERANCE

Lactose intolerance is the inability to digest and absorb lactose, the main carbohydrate in milk. It stems from an insufficiency of the enzyme lactase. (See [Understanding lactase insufficiency.](#))

Lactose intolerance may be congenital (rare) or acquired. In primary acquired lactose intolerance, the most common form, lactase levels start to decline between ages 2 and 3. By the time the patient reaches adolescence or early adulthood, lactase levels are decreased by about 90% of neonatal levels. This deficiency continues for life.

CULTURAL TIP The incidence of lactose intolerance is high among certain ethnic groups, including Blacks, Orientals, Native Americans, Greek Cypriots, and some Ashkenazic Jews.

Causes

Both congenital and primary acquired lactose intolerance are thought to have a genetic basis.

Secondary acquired lactose intolerance may result from medical conditions, such as viral gastroenteritis, inflammatory bowel disease, celiac and sprue syndromes, and intestinal parasites, which disrupt the intestinal mucosa.

Lactose intolerance can also stem from medications that cause GI disturbances (broad-spectrum antibiotics, colchicine, and certain chemotherapeutic drugs, such as antimetabolites). Ionizing radiation to the abdomen and surgery, such as small-bowel resection (with removal of some lactase-producing mucosa) or gastrectomy (with dumping syndrome), can also cause lactose intolerance. The effects may be temporary or permanent.

Complications

Lactose intolerance with resulting diarrhea can lead to dehydration, especially in infants and young children.

Assessment findings

The patient's history may reveal a pattern of GI signs and symptoms following ingestion of milk products. This may be associated with a recent dietary change such as a pregnant woman's increase in milk intake. Or the patient may have a history of a medical disorder or treatment that disrupts the GI mucosa.

Typically, the patient complains of diarrhea, abdominal cramping, discomfort, distention, flatulence, and borborygmus (intestinal rumbling).

Inspection may reveal abdominal distention and nonverbal signs of patient distress, such as doubling over or holding the abdomen. Rectal tissue irritation and excoriation related to diarrhea may be noted. Auscultation may reveal hyperactive bowel sounds.

Diagnostic tests

Lactose challenge testing is performed when lactose intolerance is suspected. In this test, the patient drinks a quart of skim milk on an empty stomach and notes any symptoms that develop within 4 hours. If the patient is lactase deficient, such symptoms as diarrhea and bloating occur within minutes to hours.

Lactose-free diet testing involves eliminating lactose from the patient's diet for a period of time, such as 5 days. If he becomes asymptomatic, the diagnosis is upheld.

Lactose tolerance testing is performed if the patient has a complicating disorder, such as celiac disease or gastroenteritis. In this test, a blood sample is taken after the patient has fasted overnight. Then the patient ingests a specified oral lactose load. Serum glucose levels are taken on blood samples drawn at specified intervals following lactose ingestion and on the fasting blood sample. A minimal increase (less than 20 mg/dl) in the serum glucose level and GI symptoms (cramping, flatulence, and perhaps diarrhea) confirm lactase deficiency.

Breath hydrogen analysis, a more sensitive and specific noninvasive test, is used to measure excess hydrogen exhalation, resulting from bacterial fermentation of lactose in the colon. (Hydrogen from the colon passes to the blood and then to the lungs.) Increased hydrogen content of expired air confirms lactose intolerance.

Small-bowel biopsy, rarely used, is used to determine whether lactose intolerance is primary or secondary. Only the secondary form shows abnormal epithelium.

Treatment

For an infant with temporary lactose intolerance, a lactose-free formula may be substituted for breast milk or milk-based formula. Older children and adults with temporary lactose intolerance must eliminate all milk products from the diet until the causative disorder improves.

Patients with genetic lactase deficiency must limit dietary lactose to the level they can comfortably tolerate. Some patients benefit from commercially available lactase enzyme products (LactAid, Lactrase), which may be added to milk or purchased ready to use. The commercial lactase reduces the lactose to glucose and galactose. Lactase enzyme capsules are also available.

Lactose-intolerant patients receiving tube feedings require a lactose-free formula (Resource or Ensure).

Nursing diagnoses

u Altered nutrition: Less than body requirements u Diarrhea u Impaired skin integrity u Knowledge deficit u Pain u Risk for fluid volume deficit

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's bowel function will return to normal.
- u The patient's fluid volume will remain within normal parameters.
- u The patient will maintain adequate caloric intake.
- u The patient's skin integrity will remain intact.

Nursing interventions

- u Monitor the patient's elimination patterns. Administer antidiarrheal agents as prescribed.
- u Give lactase enzyme products as prescribed.
- u Assess the patient for abdominal discomfort. Administer prescribed medication such as anticholinergics 30 to 60 minutes before meals. Encourage relaxation and diversion techniques to relieve discomfort.
- u Initiate patient care measures to protect the rectal skin and mucous membranes. For example, keep the area clean and dry, and apply protective cream as needed. Apply a local anesthetic, if necessary.
- u Assess the patient for signs of dehydration, such as poor skin turgor, tachycardia, decreased urine output, and hypotension. Monitor intake and output, and obtain daily weight. Encourage the patient to drink about 3 L of fluid daily, unless contraindicated.
- u Offer emotional support, and provide patient privacy.
- u Refer the patient to the dietitian as needed.

Patient teaching

- u Inform the patient or family about lactose intolerance and its associated signs and symptoms, risks, and treatment, especially dietary management.
- u Teach the patient and anyone who cooks or shops for him the foods that contain lactose, such as milk (whole, low-fat, skim, evaporated, condensed, buttermilk, cream), ice cream, cheese, sour cream, custards, milk-based puddings, butter, drinks prepared with chocolate or malted milk powder, cream sauces and gravies, cream-based soups, chocolate candy, instant potatoes, baked products made with milk, and frozen or canned fruits and vegetables containing lactose. Caution him to check product labels carefully for lactose content and to avoid products that list milk solids, milk sugars, whey, or casein.

PATHOPHYSIOLOGY

Understanding lactase insufficiency

Normally, the enzyme lactase hydrolyzes dietary lactose in the jejunum and proximal ileus. This hydrolysis splits lactose into glucose and galactose, which bind to glucose carriers and eventually pass into the portal vein. But if lactase levels are insufficient to split the lactose, a chain of effects is triggered as shown in this flowchart.

- u Instruct the patient with primary acquired lactose intolerance to eliminate all sources of lactose from his diet until he is free of symptoms. (This usually takes about 3 weeks.) Describe how to increase lactose ingestion gradually until he reaches his tolerance threshold. Explain that he needs to remain on a low-lactose diet for the rest of his life, but encourage him to gradually experiment with different lactose products over the years, noting tolerance levels.
- u Inform the patient that he may be able to tolerate milk products in which a portion of the lactose has been fermented, such as hard cheeses and yogurt. If he makes his own yogurt, suggest that he allow fermentation to continue beyond the usual time to reduce lactose content. Live-culture yogurt contains its own lactase, which is activated in the duodenum and continues the lactose ingestion.
- u Explain to the patient or family how to use lactase enzyme products.
- u Teach the patient how to avoid vitamin D and calcium deficiencies. Lactose-free sources of vitamin D include enzyme-treated milk, saltwater fish and their oils, lactose-free margarine, eggs, and exposure to sunlight. Sources of calcium for lactose-intolerant patients include enzyme-treated milk; dark green, leafy vegetables; dried beans; canned sardines and salmon (with small edible bones); almonds; and tofu. Some patients can tolerate cheeses, such as aged natural cheddar, Gouda, and Edam, which are lower in lactose but high in calcium.

PHENYLKETONURIA

Phenylketonuria (PKU) is an inborn error in amino acid (specifically phenylalanine) metabolism. It results in high serum levels of phenylalanine, increased urine concentrations of phenylalanine and its by-products, cerebral damage, and mental retardation. It's also called phenylalaninemia and phenylpyruvic oligophrenia. The disorder occurs in about 1 in 14,000 births in the United States. (About 1 person in 60 is an asymptomatic carrier.) PKU has a low incidence in Finland and among Ashkenazic Jews and American Blacks. Incidence is high among the Irish and Scottish.

Although blood phenylalanine levels approach normal at birth, they begin to increase within a few days. By the time they reach significant levels (about 30mg/dl), cerebral damage has begun. Such irreversible damage probably is complete by age 2 or 3. Early detection and treatment can minimize cerebral damage.

Causes

PKU is transmitted through an autosomal recessive gene. Patients with classic PKU, the most common and clinically important of the hyperphenylalaninemias, have almost totally deficient activity of phenylalanine hydroxylase, an enzyme that acts as a catalyst in the conversion of phenylalanine to tyrosine. As a result, phenylalanine accumulates in the blood and urine, and reduced tyrosine formation results.

Complications

Phenylalanine accumulation causes mental retardation.

Assessment findings

The patient may have a family history of PKU. Typically, the history reveals no apparent abnormalities at birth. By age 4 months, the untreated child begins to show signs of arrested brain development, including mental retardation and, later, personality disturbances (schizoid and antisocial personality patterns and uncontrollable temper). About one-third of patients have a history of seizures, which usually begin between ages 6 and 12 months. Many patients also show a precipitous decrease in IQ in the first year of life.

On inspection, the patient typically has a lighter complexion than unaffected siblings and may have blue eyes. He may exhibit macrocephaly, eczematous skin lesions, or dry, rough skin. He's usually hyperactive and irritable; shows purposeless, repetitive motions; and has an awkward gait. A musty odor from the skin and urinary excretion of phenylacetic acid may also be noted.

Diagnostic tests

Most states require screening for PKU at birth; the Guthrie test on a capillary blood sample (bacterial inhibition assay) is used to reliably detect the disorder. Because phenylalanine levels may be normal at birth, the infant should be evaluated after he has begun protein feedings. With PKU, levels are usually abnormally high by day 4.

More quantitative fluorometric or chromatographic assays provide additional diagnostic information.

Treatment

To prevent or minimize brain damage, phenylalanine blood levels are kept between 3 and 9 mg/dl by restricting dietary intake of the amino acid phenylalanine. During the first month of life, a special, lowphenylalanine, amino acid mixture is substituted for most of the protein in the diet, supplemented with a small amount of natural foods. An enzymatic hydrolysate of casein, such as Lofenalac powder or Progestimil Powder, is substituted for milk in the diets of affected infants. Dietary restrictions will probably continue throughout life.

Such a diet calls for close monitoring. The body doesn't make phenylalanine, so overzealous dietary restrictions can induce phenylalanine deficiency, causing lethargy, anorexia, anemia, rashes, and diarrhea.

Nursing diagnoses

- u Altered growth and development
- u Ineffective family coping: Potential for growth
- u Knowledge deficit
- u Risk for altered parenting
- u Risk for injury

Key outcomes

- u The patient will meet growth and development requirements and milestones.
- u The patient won't develop complications.
- u Family members will express an understanding of the disorder and treatment regimen.
- u Family members will form a bond with the child and develop appropriate attachments.

Nursing interventions

- u If the child is experiencing seizures or has some mental dysfunction, implement safety measures to prevent injury. Refer the parents and child to appropriate community resources.

Patient teaching

- u Teach preventative measures to the public and those at risk for PKU. (See [Preventing phenylketonuria.](#))
- u Teach the parents and child about PKU, and provide emotional support and counseling. (Psychological and emotional problems may result from the difficult dietary restrictions.)
- u Teach the child and his parents about the critical importance of adhering to his diet. The child must avoid bread, cheese, eggs, flour, meat, poultry, fish, nuts, milk, legumes, and aspartame (NutraSweet). He needs frequent tests for urine phenylpyruvic acid and blood phenylalanine levels to evaluate the effectiveness of the diet.
- u As the child grows older and is supervised less closely, his parents have less control over what he eats. As a result, deviation from the restricted diet becomes more likely and so does the risk of further brain damage. Encourage parents to allow the child some choices in the kinds of low-protein foods he eats; this will help make him feel trusted and more responsible.
- u Teach parents about normal physical and mental growth and development to help them recognize any developmental delay from excessive phenylalanine intake.

PORPHYRIAS

Porphyrias is an umbrella term for metabolic disorders that affect the biosynthesis of heme (a component of hemoglobin) and cause excessive production and excretion of porphyrins or their precursors. Porphyrins, which are present in all protoplasm, play a role in energy storage and use. The classification of porphyrias depends on the site of excessive porphyrin production: They may be erythropoietic (erythroid cells in bone marrow), hepatic (in the liver), or erythrohepatic (in bone marrow and liver).

PREVENTION

Preventing phenylketonuria

The following measures are helpful in preventing phenylketonuria (PKU):

- u Routinely screen infants for PKU because detection and control of phenylalanine intake soon after birth can prevent severe mental retardation.
- u Refer classic phenylketonuric females who reach reproductive age for genetic counseling because recent research indicates that their offspring may have a higher than normal incidence of brain damage, microcephaly, and major congenital malformations (especially of the heart and central nervous system). Such damage may be prevented with a low-phenylalanine diet begun before conception and continued throughout pregnancy.

Causes

Porphyrias are inherited as autosomal dominant traits, except for Günther's disease, which is an autosomal recessive trait, and toxic-acquired porphyria, which usually results from lead ingestion or lead exposure. Enzymatic defects occurring in the heme synthetic pathway cause porphyrias.

Complications

Hepatic porphyrias may result in neurologic and hepatic dysfunction. Acute intermittent porphyria may result in flaccid paralysis, respiratory paralysis, and death. Erythropoietic porphyrias may cause hemolytic anemia.

Assessment findings

Clinical findings vary widely, depending on the type of porphyria. (See [Clinical variants of porphyria.](#))

A patient with hepatic porphyria may complain of mild or severe abdominal pain and, possibly, nausea, vomiting, and constipation. Many patients with porphyrias also report photosensitivity. The patient history may help pinpoint precipitating factors, such as the use of certain medications, hormonal changes that occur during the menstrual and premenstrual cycles, infection, and malnutrition.

ADVANCED PRACTICE

Clinical variants of porphyria

PORPHYRIA	CLINICAL FINDINGS	TREATMENT
Erythropoietic porphyria		
<i>Günther's disease</i> <ul style="list-style-type: none"> Usual onset before age 5 Extremely rare 	<ul style="list-style-type: none"> Red urine (earliest, most characteristic sign); severe cutaneous photosensitivity, leading to vesicular or bullous eruptions on exposed arm and eventual scarring and ulceration Hypertrichosis Brown or red-stained teeth Splenomegaly, hemolytic anemia 	<ul style="list-style-type: none"> Beta carotene to reduce photosensitivity Anti-inflammatory ointments Prednisone to reverse anemia Packed red blood cells to inhibit erythropoiesis and excreted porphyrins Hemin for recurrent attacks Splenectomy for hemolytic anemia Topical dihydroxyacetone and lawson sunscreen filter Oral cholestyramine and charcoal to reduce intestinal reabsorption of porphyrins
Erythrohepatic porphyria		
<i>Protoporphyria</i> <ul style="list-style-type: none"> Usually affects children More common in males 	<ul style="list-style-type: none"> Photosensitive dermatitis Hemolytic anemia Chronic hepatic disease 	<ul style="list-style-type: none"> Avoidance of causative factors Beta carotene to reduce photosensitivity
<i>Toxic-acquired porphyria</i> <ul style="list-style-type: none"> Usually affects children Significant mortality 	<ul style="list-style-type: none"> Acute, colicky pain Anorexia, nausea, vomiting Neuromuscular weakness Behavioral changes Seizures, coma 	<ul style="list-style-type: none"> Chlorpromazine I.V. (25 mg every 4 to 6 hours during an acute attack) to relieve pain and GI symptoms Avoidance of lead exposure
Hepatic porphyriay		
<i>Acute intermittent porphyria</i> <ul style="list-style-type: none"> Most common form More prevalent in females, usually between ages 15 and 40 	<ul style="list-style-type: none"> Colicky abdominal pain with fever, general malaise, and hypertension Peripheral neuritis; behavior changes, possibly leading to frank psychosis Respiratory paralysis possible 	<ul style="list-style-type: none"> Chlorpromazine I.V. to relieve abdominal pain and control psychic abnormalities; meperidine for severe pain Avoidance of precipitating medications, infections, alcohol, and fasting Hemin for recurrent attacks High-carbohydrate diet I.V. glucose
<i>Variegate porphyria</i> <ul style="list-style-type: none"> Onset between ages 30 and 50 Occurs almost exclusively among South African whites Affects males and females equally 	<ul style="list-style-type: none"> Skin lesions, fragile skin in exposed areas Hypertrichosis of face and temples Hyperpigmentation Abdominal pain during acute attack Neuropsychiatric manifestations 	<ul style="list-style-type: none"> High-carbohydrate diet Avoidance of sunlight, or wearing protective clothing and using sunscreen when avoidance isn't possible Hemin for recurrent attacks
<i>Porphyria cutanea tarda</i> <ul style="list-style-type: none"> Most common in men ages 40 to 60 Highest incidence in South Africans 	<ul style="list-style-type: none"> Facial pigmentation Red-brown urine Photosensitivity dermatitis Hypertrichosis 	<ul style="list-style-type: none"> Avoidance of precipitating factors (alcohol, estrogen, sunlight exposure, and iron) Phlebotomy at 2-week intervals to lower serum iron level
<i>Hereditary coproporphyria</i> <ul style="list-style-type: none"> Rare Affects males and females equally 	<ul style="list-style-type: none"> Asymptomatic or mild neurologic, abdominal, or psychiatric symptoms 	<ul style="list-style-type: none"> High-carbohydrate diet Avoidance of barbiturates Hemin for recurrent attacks

Neurologic examination may reveal paresthesia, hypoesthesia, neuritic pain, psychosis, and seizures.

Depending on the type of porphyria, inspection findings may include skin lesions (possibly associated with erythema, altered pigmentation, and edema in areas exposed to light); urine that becomes darker when left standing in light and air; and neurologic signs, such as wristdrop and footdrop. If hemolytic anemia occurs, expect to find splenomegaly on palpation.

In a patient with acute intermittent porphyria, auscultation may reveal wheezing and dyspnea, compounded by the patient's anxiety. During an acute attack, fever may occur.

Diagnostic tests

In acute intermittent porphyria, the Watson-Schwartz test result may be positive for porphobilinogen in the urine; the ion exchange chromatography test may identify aminolevulinic acid (ALA) in the urine.

In variegate porphyria, protoporphyrin and coproporphyrin may be positive in the stools. With hereditary coproporphyria, large amounts of coproporphyrin appear in the stools and, to a lesser extent, in the urine.

Porphyria cutanea tarda results in increased excretion of uroporphyrins; the amount of fecal porphyrins varies.

With Günther's disease, porphyrins are found in the urine, especially uroporphyrin I.

With erythropoietic protoporphyria, fluorescent microscopy is used to confirm the diagnosis by revealing excess protoporphyrin in the red blood cells.

A urine lead level of 0.2 mg/L helps confirm toxic acquired porphyria.

Other laboratory values may include increased serum iron levels in porphyria cutanea tarda. Leukocytosis, elevated bilirubin and alkaline phosphatase levels, and hyponatremia occur in acute intermittent porphyria.

Treatment

Depending on the type of porphyria, treatment may include the administration of beta carotene to reduce photosensitivity, chlorpromazine I.V. to treat mild abdominal discomfort, meperidine to treat severe pain, levulose I.V. to increase carbohydrate intake, and hemin (an enzyme inhibitor derived from processed red blood cells) to suppress hepatic ALA and porphobilinogen. Splenectomy may be performed to treat hemolytic anemia. Patients with photosensitivity should avoid direct sunlight or use sunscreen preparations. A high carbohydrate level with restricted fluid intake decreases urinary excretion of the enzymes 5-ALA synthase and hydroxymethylbilane (also called HMB, porphobilinogen, deaminase, uroporphyrinogen I synthase), inhibiting the release of antidiuretic hormone.

Nursing diagnoses

- u Constipation
- u Impaired gas exchange
- u Impaired skin integrity
- u Knowledge deficit
- u Pain
- u Risk for injury

WARNING

Drugs that aggravate porphyria

Make sure the patient with porphyria doesn't receive any of the following drugs, which are known to precipitate signs and symptoms of porphyria:

- u alcohol
- u aminopyrine
- u barbiturates
- u carbamazepine
- u carisoprodol
- u chloramphenicol
- u chlordiazepoxide
- u danazol
- u diazepam
- u ergot alkaloids
- u estrogens
- u glutethimide
- u griseofulvin
- u imipramine
- u meprobamate
- u methsuximide
- u methyldopa
- u methyprylon
- u pentazocine
- u phenytoin
- u progesterones
- u sulfonamides
- u tolbutamide.

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will maintain adequate ventilation.
- u The patient's skin integrity will remain intact.
- u The patient will avoid complications.
- u The patient's bowel movements will return to normal.

Nursing interventions

- u Before administering medications to the patient, make certain the drugs don't precipitate an acute attack. (See [Drugs that aggravate porphyria.](#))
- u Administer hemin by a large arm vein or central venous catheter as ordered. Overdosage can lead to renal shutdown.
- u Provide emotional support, and encourage the patient to verbalize his concerns about his condition.

For acute intermittent porphyria:

- u Provide active and passive range-of-motion exercises every 8 hours. Position the patient's body in proper alignment, using splinting as necessary. Assess respiratory status every 2 hours; respiratory depression or paralysis requires mechanical ventilation.
- u Observe for signs and symptoms of decreased GI motility, resulting in distention, ileus, vomiting, and constipation.
- u Take safety precautions as indicated. For example, use padded side rails, and keep an oral airway at the bedside if seizure activity is possible.
- u If the patient is experiencing an acute attack, administer comfort measures, including mouth care, skin care, and massage every 2 hours, with positioning and pulmonary hygiene. Administer analgesics as ordered.

Patient teaching

- u Warn the patient against excessive sun exposure.
- u Stress the importance of wearing a medical identification bracelet or necklace.
- u If the patient has toxic-acquired porphyria, discuss sources of lead, and refer him to resources that can be used to identify such sources in the home.
- u Warn the patient to avoid precipitating factors, including crash dieting, fasting, and the use of specific drugs, such as alcohol, estrogens, and barbiturates. Teach stress-management techniques because emotional stress may also precipitate an acute attack. Discuss measures to prevent infection, another precipitating factor.
- u Encourage a high-carbohydrate diet to provide sufficient calories without taxing the liver to break down proteins.

TAY-SACHS DISEASE

Tay-Sachs disease, the most common lipid storage disease, results from a congenital enzyme deficiency. It occurs in fewer than 100 infants born each year in the United States. It strikes people of Ashkenazic Jewish ancestry about 100 times more often than the general population, occurring in about 1 in 3,600 live births in this ethnic group. About 1 in 30 Ashkenazi Jews, French Canadians, and American Cajuns are heterozygous carriers of this defective gene. If two such carriers have children, each of their offspring has a 25% chance of having Tay-Sachs disease.

The disease is characterized by progressive mental and motor deterioration and is always fatal, usually before age 5.

Causes

Tay-Sachs disease (also known as GM₂ gangliosidosis) is an autosomal recessive disorder in which the enzyme hexosaminidase A is deficient. This enzyme is necessary for metabolism of gangliosides, water-soluble glycolipids found primarily in central nervous system (CNS) tissues. Without hexosaminidase A, accumulating lipid pigments distend and progressively destroy and demyelinate CNS cells.

Complications

Starting at about age 2, the patient with Tay-Sachs disease contracts recurrent bronchopneumonia, which is usually fatal before age 5.

Assessment findings

Usually, the patient has a familial history of Tay-Sachs disease. The patient history typically reveals a normal appearance at birth (with the possible exception of an exaggerated Moro's reflex) and onset of clinical signs and symptoms between ages 5 and 6 months, followed by progressive deterioration, with psychomotor retardation, blindness, and dementia.

On inspection, the 3- to 6-month-old infant appears apathetic and displays an augmented response to loud sounds. Progressive weakness of the neck, trunk, arm, and leg muscles prevents the child from sitting up or lifting his head. He has difficulty turning over, can't grasp objects, and has progressive vision loss.

By 18 months, the infant may have a history of seizures, generalized paralysis, and spasticity. Although the infant is blind, he may hold his eyes wide open and roll his eyeballs. His pupils are always dilated. Decerebrate rigidity and a complete vegetative state follow.

Measurement of the head circumference may show enlargement. Pupillary testing finds no reaction to light. Ophthalmoscopic examination may show optic nerve atrophy and a distinctive cherry red spot on the retina.

A child who survives bouts of recurrent broncho-pneumonia may develop ataxia and progressive motor retardation between ages 2 and 8.

The juvenile form of Tay-Sachs disease generally appears between ages 2 and 5 as a progressive deterioration of psychomotor skills and gait. Patients with this type of disease can survive to adulthood.

Diagnostic tests

Serum analysis showing deficient hexosaminidase A is typically the key to diagnosis. Diagnostic screening is essential for all couples of Ashkenazic Jewish ancestry and for others with a family history of the disease. A simple blood test evaluating hexosaminidase A levels can be used to identify carriers.

If carriers wish prenatal diagnosis, amniocentesis or chorionic villus biopsy can be used to detect hexosaminidase A deficiency and, thereby, Tay-Sachs disease in the fetus.

For two-carrier parents using invitro fertilization to achieve pregnancy, genetic testing has been attempted with some success. Healthy embryos are transferred to the woman's uterus.

Treatment

Tay-Sachs disease has no known cure. Supportive treatment includes tube feedings using nutritional supplements, suctioning and postural drainage to remove secretions, skin care to prevent pressure ulcers when the child becomes bedridden, and mild laxatives to relieve neurogenic constipation. Unfortunately, anticonvulsants usually fail to prevent seizures. Because these children need round-the-clock physical care, they commonly require long-term care in special facilities.

Nursing diagnoses

u Anticipatory grieving u Impaired physical mobility u Ineffective airway clearance u Ineffective family coping: Disabling u Knowledge deficit u Risk for impaired skin integrity u Risk for injury

Key outcomes

- u The patient will maintain a patent airway.
- u The patient will perform activities of daily living within the confines of the disease process.
- u The family members will express an understanding of the disease process and treatment regimen.
- u Family members will seek outside sources to assist with coping and adjustment to the patient's situation.
- u The patient will avoid complications.

Nursing interventions

- u Help the family deal with the infant's inevitably progressive illness and death.
- u Refer parents for genetic counseling, and stress the importance of amniocentesis in future pregnancies. Refer siblings for screening to determine whether they're carriers. If they are carriers and are adults, refer them for genetic counseling, but stress that the disease isn't transmitted to offspring if they don't marry another carrier.
- u Because parents may feel excessive stress or guilt about their child's illness, impending death, and the emotional and financial burden it places on them, refer them for psychological counseling, if indicated.
- u Implement measures to prevent skin breakdown in the child, provide for adequate nutrition, and maintain a patent airway. Implement seizure precautions to prevent injury.

Patient teaching

- u If the parents plan to care for their child at home, teach them how to do suctioning, postural drainage, and tube feeding. Also teach them how to give good skin care to prevent pressure ulcers.
- u Refer parents to the National Tay-Sachs and Allied Diseases Association for more information on this disease.

Fluid, electrolyte, and acid-base disorders

The mechanisms of fluid, electrolyte, and acid-base balance maintain homeostasis by controlling such body functions as the heart rate, hematopoiesis, blood pressure, body temperature, respiration, and glandular secretion. With prompt treatment, the prognosis for most types of homeostatic imbalance is good.

CALCIUM IMBALANCE

Calcium plays an indispensable role in cell permeability, the formation of bones and teeth, blood coagulation, transmission of nerve impulses, and normal muscle contraction. Nearly all of the body's calcium is in the bones. The remaining exists in serum in three forms: ionized or free calcium (the only active, or available, calcium), calcium bound to protein, and calcium complexed with citrate or other organic ions.

The maintenance of ionized calcium in the serum is critical to healthy neurologic function. The parathyroid glands regulate ionized calcium and determine its resorption into bone, absorption from the GI mucosa, and excretion in urine and stools.

Causes

Hypocalcemia may result from:

- inadequate intake of calcium and vitamin D, in which inadequate levels of vitamin D inhibit intestinal absorption of calcium
- hypoparathyroidism as a result of injury, disease, or surgery that decreases or eliminates secretion of parathyroid hormone (PTH), which is necessary for calcium absorption and normal serum calcium levels
- malabsorption or loss of calcium from the GI tract, caused by increased intestinal motility from severe diarrhea or laxative abuse (Malabsorption of calcium from the GI tract can also result from inadequate levels of vitamin D or PTH, or a reduction in gastric acidity, decreasing the solubility of calcium salts.)
- severe infections or burns, in which diseased and burned tissue traps calcium from the extracellular fluid
- alkalosis, in which calcium forms a complex with bicarbonate, causing decreased ionized calcium and inducing symptoms of hypocalcemia
- pancreatic insufficiency, which can cause malabsorption of calcium and subsequent calcium loss in stools (In acute pancreatitis, hypocalcemia varies in degree with the severity of the disorder. The exact cause of hypocalcemia in this instance is unknown.)
- renal failure, resulting in excessive excretion of calcium (can also occur with the use of loop diuretics)
- hypomagnesemia, which causes decreased PTH secretion and blocks the peripheral action of that hormone
- hyperphosphatemia, which causes calcium levels to decrease as phosphorus levels increase
- extensive administration of citrated blood, which may result in citrate binding with calcium.

Hypercalcemia may result from:

- hyperparathyroidism, a primary cause, which increases serum calcium levels by promoting calcium absorption from the intestine, resorption from bone, and reabsorption from the kidneys
- hypervitaminosis D, which can promote increased absorption of calcium from the intestine
- some cancers, such as multiple myeloma, lymphoma, squamous cell carcinoma of the lung, and breast cancer, which raise serum calcium levels by destroying bone or by releasing PTH or a PTH-like substance, osteoclast-activating factor, prostaglandins and, perhaps, a vitamin D–like sterol
- multiple fractures and prolonged immobilization, which release bone calcium and increase the serum calcium level.

Other causes of hypercalcemia include milk-alkali syndrome, renal failure, sarcoidosis, hyperthyroidism, adrenal insufficiency, thiazide diuretics, and excessive administration of calcium during cardiopulmonary arrest.

Complications

Severe hypocalcemia can lead to laryngeal spasm, seizures and, possibly, respiratory arrest. Cardiac arrhythmias may also occur.

In hypercalcemia, serum calcium levels greater than 13.5 mg/dl may cause coma and cardiac arrest. Hypercalcemia may also lead to renal calculi.

Assessment findings

The history of a patient with hypocalcemia may disclose such risk factors as hypothyroidism and renal failure. The patient may report digital and perioral paresthesia and muscle cramps. Inspection may reveal twitching, carpopedal spasm, tetany, and seizures. Auscultation sometimes detects cardiac arrhythmias. A physical examination may uncover reliable indicators of hypocalcemia, including hyperactive reflexes, a positive Trousseau's sign, and a positive Chvostek's sign.

A patient with hypercalcemia may have a history of risk factors, such as excessive ingestion of vitamin D and prolonged immobilization. He may complain of lethargy, weakness, anorexia, constipation, nausea, vomiting, and polyuria. Family members may report personality changes.

During assessment, the patient may appear confused or, in severe cases, comatose. Neuromuscular assessment may reveal muscle weakness, with hyporeflexia and decreased muscle tone. (See [Signs and symptoms of calcium imbalance.](#))

Diagnostic tests

Total serum calcium levels are less than 8.5 mg/dl in hypocalcemia; greater than 10.5 mg/dl in hypercalcemia.

Ionized serum calcium levels less than 4.5 mg/dl confirm hypocalcemia; levels greater than 5.3 mg/dl confirm hypercalcemia. (Because about one-half of serum calcium is bound to albumin, changes in serum protein levels must be considered when interpreting serum calcium levels.)

Sulkowitch's urine test shows increased calcium precipitation in hypercalcemia.

Electrocardiogram (ECG) results are significant for lengthened QT interval, prolonged ST segment, and arrhythmias in hypocalcemia. In hypercalcemia, a shortened QT interval is seen. Ventricular arrhythmias may occur with severe hypercalcemia.

Treatment

The aim of treatment is to correct acute imbalance, followed by maintenance therapy and correction of the underlying cause.

A patient with mild hypocalcemia may require only a diet adjustment to allow adequate intake of calcium, vitamin D, and protein, possibly with oral calcium supplements.

Acute hypocalcemia is an emergency that needs immediate correction by I.V. administration of calcium gluconate, which is usually preferable to calcium chloride. If hypocalcemia is related to hypomagnesemia, magnesium replacement is necessary because hypocalcemia often doesn't respond to calcium therapy alone.

Patients with chronic hypocalcemia also require vitamin D supplements to facilitate GI calcium absorption. To correct mild deficiency, the amount of vitamin D in most multivitamin preparations is adequate. For severe deficiency, vitamin D is used in four forms: ergocalciferol (vitamin D₂), cholecalciferol (vitamin D₃), calcitriol, and dihydrotachysterol, a synthetic form of vitamin D₂.

Treatment for patients with hypercalcemia that produces no symptoms may consist only of managing the underlying cause. Treatment of hypercalcemia that produces symptoms primarily eliminates excess serum calcium through hydration with normal saline solution, which promotes calcium excretion in urine. Loop diuretics, such as

ethacrynic acid and furosemide, also promote calcium excretion. (Thiazide diuretics are contraindicated in hypercalcemia because they inhibit calcium excretion.)

Corticosteroids, such as prednisone and hydrocortisone, are helpful in treating sarcoidosis, hypervitaminosis D, and certain tumors. Mithramycin can also lower serum calcium levels and is especially effective against hypercalcemia secondary to certain tumors. Calcitonin may also be helpful in certain instances. The administration of I.V. phosphates is potentially dangerous and is used only when other treatments prove ineffective.

Nursing diagnoses

- u Altered tissue perfusion (cardiopulmonary)
- u Anxiety
- u Fear
- u Decreased cardiac output
- u Impaired gas exchange
- u Knowledge deficit
- u Risk for injury

Key outcomes

- u The patient will maintain adequate cardiac output.
- u The patient's vital signs will remain stable.
- u The patient will maintain adequate ventilation.
- u The patient will avoid complications.
- u The patient and family members will express an understanding of the disorder and treatment regimen.

Signs and symptoms of calcium imbalance		
DYSFUNCTION	HYPOCALCEMIA	HYPERCALCEMIA
Central nervous system	Anxiety, irritability, twitching around mouth, laryngospasm, seizures, Chvostek's sign, Trousseau's sign	Drowsiness, lethargy, headaches, depression or apathy, irritability, confusion, coma
Musculoskeletal	Paresthesia (tingling and numbness of the fingers), tetany or painful tonic muscle spasms, facial spasms, abdominal cramps, muscle cramps, spasmodic contractions	Weakness, muscle flaccidity, bone pain, pathologic fractures
Cardiovascular	Arrhythmias, hypotension	Signs of heart block, cardiac arrest in systole, hypertension
GI	Increased GI motility, diarrhea	Anorexia, nausea, vomiting, constipation, dehydration, polydipsia
Other	Blood clotting abnormalities (rare)	Renal polyuria, flank pain, kidney stones and, eventually, azotemia

Nursing interventions

For hypocalcemia:

- u Watch for the disorder in patients at risk, such as those receiving massive transfusions of citrated blood, and in those with chronic diarrhea, severe infections, and insufficient dietary intake of calcium and protein (especially elderly patients).
- u Monitor serum calcium levels every 12 to 24 hours and report any decrease.
- u When giving calcium supplements, frequently check pH level because an alkalotic state that exceeds 7.45 pH inhibits calcium ionization.
- u Check for Trousseau's and Chvostek's signs, and report positive signs to the doctor.
- u Monitor ECG results for signs of worsening hypocalcemia. Notify the doctor if ventricular arrhythmias or heart block develops.
- u Using a volumetric infusion pump, administer calcium gluconate I.V. slowly, in dextrose 5% in water (never in normal saline solution, which encourages renal calcium loss). Don't infuse more than 1 g/hour except in emergencies.
- u Don't add calcium gluconate I.V. to solutions containing bicarbonate; it will precipitate. When administering calcium solutions, watch for anorexia, nausea, and vomiting—possible signs of overcorrection of hypercalcemia.
- u Observe the I.V. site for signs of infiltration because calcium can cause tissue sloughing.
- u If the patient is receiving calcium chloride, watch for abdominal discomfort.
- u Monitor the patient closely for a possible drug interaction if he's receiving digoxin with large doses of oral calcium supplements; watch for signs and symptoms of digitalis toxicity (anorexia, nausea, vomiting, yellow vision, and cardiac arrhythmias). Administer oral calcium supplements 1 to ½ hours after meals or with milk, if GI upset occurs.
- u Provide a quiet, safe, stress-free environment for the patient. Observe seizure precautions for patients with severe hypocalcemia that may lead to seizures.
- u Assess the patient's respiratory rate, depth, pattern, and rhythm. Be alert for stridor, dyspnea, or crowing. For the symptomatic patient, keep a tracheostomy tray and manual resuscitation bag at the bedside in case of laryngeal spasm.

For hypercalcemia:

- u Monitor serum calcium levels frequently. Report increasing levels.
- u Increase fluid intake to dilute calcium in serum and urine and to prevent renal damage and dehydration.
- u Watch for signs of heart failure in patients receiving normal saline solution diuresis therapy.
- u Administer loop diuretics (not thiazide diuretics) as ordered. Monitor intake and output, and strain urine for renal calculi. Provide acid-ash drinks, such as cranberry juice, because calcium salts are more soluble in acid than in alkali.
- u Check ECG results and vital signs frequently. Observe for arrhythmias if hypercalcemia is severe.
- u If the patient is receiving a digitalis glycoside, watch for signs of toxicity, such as anorexia, nausea, vomiting, and an irregular pulse.
- u Ambulate the patient as soon as possible. Handle the patient with chronic hypercalcemia gently to prevent pathologic fractures. If the patient is bedridden, reposition him frequently, and encourage range-of-motion exercises to promote circulation and prevent urinary stasis and calcium loss from bone.
- u Provide a safe environment. Keep the bed's side rails raised and the bed in the lowest position with the wheels locked.
- u Frequently assess the patient's level of consciousness. Orient him as needed.

Patient teaching

For patients with hypocalcemia:

- u To prevent hypocalcemia, advise all patients—especially elderly patients—to eat foods rich in calcium, vitamin D, and protein, such as fortified milk and cheese. Explain how important calcium is for normal bone formation and blood coagulation. Discourage chronic use of laxatives.
- u If the patient requires oral calcium preparations or vitamin D supplements, make sure he understands his medication regimen.

For patients with hypercalcemia:

- u To prevent recurrence of hypercalcemia, suggest a low-calcium diet with increased fluid intake.
- u Review nonprescription medications that are high in calcium, and advise the patient to avoid these. Also caution him not to take megadoses of vitamin D.

- u Stress the importance of increased fluid intake (up to 3 L in nonrestricted patients) to minimize the possibility of renal calculi formation.

CHLORIDE IMBALANCE

Hypochloremia and hyperchloremia are chloride imbalances. A deficient serum level of the anion chloride results in hypochloremia; an excessive serum chloride level causes hyperchloremia. A predominantly extracellular anion, chloride accounts for two-thirds of all serum anions.

Chloride—secreted by the stomach mucosa as hydrochloric acid—provides an acid medium conducive to digestion and activation of enzymes. It also participates in maintaining acid-base and body water balances, influences the osmolality or tonicity of extracellular fluid (ECF), plays a role in oxygen and carbon dioxide exchange in red blood cells, and helps activate salivary amylase (which, in turn, activates the digestive process).

Causes

Hypochloremia may result from:

- u decreased chloride intake or absorption, as in low dietary sodium intake, sodium deficiency, potassium deficiency, and metabolic alkalosis; prolonged use of mercurial diuretics; or administration of I.V. dextrose without electrolytes
- u excessive chloride loss, resulting from prolonged diarrhea or diaphoresis; or loss of hydrochloric acid in gastric secretions due to vomiting, gastric suctioning, or gastric surgery.

Hyperchloremia may result from:

- u excessive chloride intake or absorption (as in hyperingestion of ammonium chloride or ureterointestinal anastomosis) allowing reabsorption of chloride by the bowel
- u hemoconcentration, caused by dehydration
- u compensatory mechanisms for other metabolic abnormalities, as in metabolic acidosis, brain stem injury causing neurogenic hyperventilation, and hyperparathyroidism.

Complications

Hypochloremia may result in depressed respirations, leading to respiratory arrest. Hyperchloremia may cause coma.

Assessment findings

The patient's history may reveal risk factors for hypochloremia or hyperchloremia.

When hypochloremia is associated with hyponatremia, physical assessment may reveal characteristic muscle weakness and twitching because renal chloride loss always accompanies sodium loss and sodium reabsorption isn't possible without chloride.

When chloride depletion results from metabolic alkalosis secondary to loss of gastric secretions, chloride is lost independently of sodium. Inspection may reveal tetany and shallow, depressed breathing. During neuromuscular assessment, you may find muscle hypertonicity.

Because of the natural affinity of sodium and chloride ions, hyperchloremia usually produces clinical effects associated with hypernatremia and resulting ECF volume excess. On inspection, you may note agitation, pitting edema, and dyspnea. Vital signs may reflect tachycardia and hypertension.

When hyperchloremia is associated with metabolic acidosis (due to base bicarbonate excretion by the kidneys), inspection may reveal deep, rapid breathing. Neurologic assessment may reveal weakness, diminished cognitive ability and, ultimately, coma.

Diagnostic tests

Serum chloride levels less than 98 mEq/L confirm hypochloremia; supportive values with metabolic alkalosis include a serum pH over 7.45 and serum carbon dioxide levels greater than 32 mEq/L.

Serum chloride levels greater than 106 mEq/L confirm hyperchloremia; with metabolic acidosis, serum pH is under 7.35 and serum carbon dioxide levels are less than 22 mEq/L.

Treatment

For patients with hypochloremia, the goal of treatment is to correct the condition that causes excessive chloride loss and to give an oral replacement such as salty broth.

When oral therapy isn't possible or when emergency measures are necessary, treatment may include I.V. administration of normal saline solution (if hypovolemia is present) or chloride-containing drugs, such as ammonium chloride to increase serum chloride levels, and potassium chloride for metabolic alkalosis.

For patients with severe hyperchloremic acidosis, treatment consists of sodium bicarbonate I.V. to raise serum bicarbonate levels and permit renal excretion of the chloride anion because bicarbonate and chloride compete for combination with sodium. For mild hyperchloremia, lactated Ringer's solution is administered; it converts to bicarbonate in the liver, thus increasing base bicarbonate to correct acidosis.

In either kind of chloride imbalance, the goal of treatment is to correct the underlying disorder.

Nursing diagnoses

u Altered thought processes u Altered tissue perfusion (cardiopulmonary) u Anxiety u Fluid volume deficit u Ineffective breathing pattern u Knowledge deficit u Risk for injury

Key outcomes

- u The patient will maintain adequate cardiac output.
- u The patient will maintain adequate ventilation.
- u The patient's vital signs will remain stable.
- u The patient's fluid volume will remain within normal parameters.
- u The patient will avoid complications.

Nursing interventions

For hypochloremia:

- u Monitor serum chloride levels frequently, particularly during I.V. therapy.
- u Watch for signs of hyperchloremia or hypochloremia. Be alert for respiratory difficulty.
- u To prevent hypochloremia, monitor laboratory results (serum electrolyte levels and arterial blood gas values) and fluid intake and output of patients who are

vulnerable to chloride imbalance, particularly those recovering from gastric surgery. Record and report excessive or continuous loss of gastric secretions. Also report prolonged infusion of dextrose in water without normal saline solution.

- u If the patient has muscle weakness, initiate measures to prevent injury. Assist the patient with ambulation. Keep personal articles within easy reach.

For hyperchloremia:

- u Check serum electrolyte levels every 3 to 6 hours. If the patient is receiving high doses of sodium bicarbonate, watch for signs of overcorrection (metabolic alkalosis, respiratory depression) or lingering signs of hyperchloremia, which indicate inadequate treatment.
- u If the patient shows altered thought processes due to hyperchloremic acidosis, provide a safe environment, and assess neurologic status frequently for signs of deterioration.
- u If sodium excess is also present, assess for signs of fluid overload.
- u Assess respiratory functioning. Rapid, deep respirations, a compensatory mechanism, may accompany hyperchloremic acidosis.
- u To prevent hyperchloremia, check laboratory results for elevated serum chloride or potassium imbalance if the patient is receiving I.V. solutions containing sodium chloride, and monitor fluid intake and output. Also, watch for signs of metabolic acidosis. When administering I.V. fluids containing lactated Ringer's solution, monitor flow rate according to the patient's age, physical condition, and bicarbonate level. Report any irregularities promptly.

Patient teaching

- u Explain all tests and procedures to the patient and family members.
- u Discuss food sources of sodium, potassium, and chloride with the patient experiencing hypochloremia.

MAGNESIUM IMBALANCE

Magnesium, the second most abundant intracellular cation, functions chiefly to enhance neuromuscular integration. Changes in magnesium level affect neuromuscular irritability and contractility. Magnesium also stimulates parathyroid hormone (PTH) secretion, thus regulating intracellular fluid calcium levels.

Magnesium also regulates skeletal muscle contraction through its influence on calcium utilization by depressing acetylcholine release at synaptic junctions. In addition, it activates many enzymes for proper carbohydrate and protein metabolism, aids in cell metabolism and the transport of sodium and potassium across cell membranes, and influences sodium, potassium, calcium, and protein levels.

Causes

Hypomagnesemia most commonly results from chronic alcoholism. The deficiency may also result from malabsorption syndromes, chronic diarrhea, prolonged nasogastric suction, or postoperative complications after bowel resection. It may follow decreased intake or administration of parenteral fluids without magnesium salts, enteral or total parenteral nutrition without adequate magnesium content, increased renal excretion associated with prolonged diuretic therapy, and cisplatin, amphotericin, tobramycin, or gentamicin therapy. It may also follow excessive loss of magnesium, as in severe dehydration and diabetic acidosis; hyperaldosteronism and hypoparathyroidism; hyperparathyroidism and hypercalcemia; and excessive release of adrenocortical hormones.

Hypermagnesemia usually results from the kidneys' inability to excrete magnesium that was either absorbed from the intestines or infused. Common causes of hypermagnesemia include chronic renal insufficiency, severe dehydration, overdose with magnesium salts, and adrenal insufficiency overuse of magnesium-containing antacids, especially with renal insufficiency. (See [Drugs that contain magnesium.](#))

Complications

Hypomagnesemia may result in transient hypo-parathyroidism, interference with the peripheral action of PTH, seizures, and confusion deteriorating to coma. Serious cardiac arrhythmias may also occur. Hypermagnesemia can cause complete heart block and respiratory paralysis.

WARNING

Drugs that contain magnesium

To avoid hypermagnesemia, don't give magnesiumcontaining drugs to a patient with renal failure or poor renal functioning. Also, instruct the patient to avoid the following nonprescription medications that contain magnesium.

Antacids

- u Aludrox
- u Camalox
- u Di-Gel
- u Gaviscon
- u Gelusil and Gelusil-II
- u Maalox and Maalox Plus
- u Mylanta and Mylanta-II
- u Riopan
- u Simeco
- u Tempo

Laxatives

- u Magnesium citrate
- u Magnesium hydroxide (Phillips' Milk of Magnesia, Haley's M-O)
- u Magnesium sulfate (Epsom Salt)

Assessment findings

Generally, a patient with hypomagnesemia exhibits neuromuscular irritability and cardiac arrhythmias. A patient with hypermagnesemia may exhibit central nervous system and respiratory depression in addition to neuromuscular and cardiac effects. (See [Recognizing magnesium imbalance.](#))

Diagnostic tests

Serum magnesium levels are analyzed to determine imbalance. Values less than 1.5 mEq/L or 1.8 mg/dl confirm hypomagnesemia; values more than 2.5 mEq/L or 3 mg/dl indicate hypermagnesemia.

Serum magnesium levels should be evaluated in combination with serum albumin levels because low albumin levels decrease the total magnesium while leaving the

amount of free ionized magnesium unchanged.

Low levels of other serum electrolytes (especially potassium and calcium) typically coexist with hypomagnesemia. In fact, unresponsiveness to correct treatment for hypokalemia strongly suggests hypomagnesemia. Similarly, elevated levels of other serum electrolytes are associated with hypermagnesemia.

Recognizing magnesium imbalance		
Hypomagnesemia and hypermagnesemia may produce the following neuromuscular, central nervous system (CNS), cardio-vascular, and GI effects.		
DYSFUNCTION	HYPOMAGNESEMIA	HYPERMAGNESEMIA
Neuromuscular	Hyperirritability, athetoid tetany, leg and foot cramps, Chvostek's sign (facial muscle spasms induced by tapping the branches of the facial nerve)	Diminished deep tendon reflexes, muscle weakness, flaccid paralysis, respiratory muscle paralysis with high magnesium levels
CNS	Mood changes, confusion, delusions, hallucinations, seizures	Drowsiness, confusion, diminished sensorium; may progress to coma
Cardiovascular	Arrhythmias	Bradycardia, weak pulse, hypotension, diffuse vasodilation, heart block, cardiac arrest with high magnesium levels
GI	Anorexia, nausea, vomiting	Nausea, vomiting

Treatment

The goal of therapy is to identify and correct the underlying cause. Therapy for patients with mild hypomagnesemia consists of dietary replacement and possibly daily oral magnesium supplements. For patients with severe hypomagnesemia, therapy includes I.V. administration of magnesium sulfate (10 to 40 mEq/L diluted in I.V. fluid). Magnesium intoxication is a possible adverse effect. Treatment requires calcium gluconate I.V.

Therapy for patients with hypermagnesemia includes increased fluid intake and loop diuretics such as furosemide with impaired renal function; calcium gluconate (10%) I.V., a magnesium antagonist, for temporary relief of serious symptoms in an emergency, along with ventilatory support; and peritoneal dialysis or hemodialysis if renal function fails or if excess magnesium can't be eliminated.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion (renal)
- u Anxiety
- u Impaired gas exchange
- u Knowledge deficit
- u Risk for injury

Key outcomes

- u The patient will maintain adequate fluid volume.
- u The patient will maintain adequate ventilation.
- u The patient's vital signs will remain stable.
- u The patient will avoid complications.
- u The patient will express an understanding of the disorder and treatment regimen.

Nursing interventions

For hypomagnesemia:

- u Watch for and report signs of hypomagnesemia in patients at risk.
- u Monitor serum electrolyte levels (including magnesium, calcium, and potassium) daily for mild deficits and every 6 to 12 hours during replacement therapy. Assess for signs associated with low serum electrolyte levels.
- u Assess for dysphagia by testing the patient's ability to swallow water before giving food or medications.
- u With severe hypomagnesemia, initiate seizure precautions, and take other measures to ensure patient safety if he is confused.
- u Closely monitor patients receiving digoxin because hypomagnesemia predisposes to digitalis toxicity.
- u Monitor for cardiac arrhythmias.
- u Monitor vital signs during I.V.replacement therapy. Infuse magnesium replacement slowly, using an I.V. controller. Watch for bradycardia, heart block, and decreased respirations. Have calcium gluconate I.V. available to reverse hypermagnesemia from overcorrection.
- u Refer the alcoholic patient to a support group.

For hypermagnesemia:

- u Watch for signs of the disorder in predisposed patients.
- u Frequently assess level of consciousness, muscle activity, and vital signs, noting hypotension and shallow respirations.
- u Monitor serum magnesium levels. Respiratory paralysis may occur when serum magnesium levels are between 10 and 15 mEq/L.
- u Keep accurate intake and output records. Provide sufficient fluids for adequate hydration and maintenance of renal function.
- u Report abnormal serum electrolyte levels immediately.
- u Carefully monitor a patient who receives digoxin and calcium gluconate simultaneously; calcium excess enhances digitalis action, predisposing the patient to digitalis intoxication.

Patient teaching

For patients with hypomagnesemia:

- u Advise the patient to eat foods high in magnesium, such as seed grains, nuts, and legumes. Inform him that fresh meat, fish, and fresh fruits usually contain small amounts of magnesium.
- u Warn a patient receiving parenteral magnesium that he may experience flushing and warmth secondary to peripheral vasodilation.
- u Advise the patient to avoid laxative or diuretic abuse; this practice may result in loss of magnesium.

For patients with hypermagnesemia:

- u Advise a patient with renal failure to check with his doctor before taking any nonprescription medication.
- u Caution the patient not to abuse laxatives and antacids containing magnesium, especially if he's elderly or has compromised renal function.

METABOLIC ACIDOSIS

Metabolic acidosis—marked by excess acid accumulation and deficient base bicarbonate—is produced by an underlying disorder. Symptoms result from the body's attempts to correct the acidotic condition through compensatory mechanisms in the lungs, kidneys, and cells.

Metabolic acidosis is more prevalent among children, who are vulnerable to acid-base imbalance because their metabolic rates are faster and their ratios of water to total body weight are lower. Severe or untreated metabolic acidosis can be fatal.

Causes

Metabolic acidosis usually results from excessive burning of fats in the absence of usable carbohydrates. Diabetic ketoacidosis, chronic alcoholism, malnutrition, or a low-carbohydrate, high-fat diet—all of which produce more keto acids than the metabolic process can handle—can cause this. Other causes include:

- ▮ anaerobic carbohydrate metabolism (lactic acidosis). A decrease in tissue oxygenation or perfusion (as occurs with pump failure after myocardial infarction or with pulmonary or hepatic disease, shock, or anemia) forces a shift from aerobic to anaerobic metabolism, causing a corresponding increase in lactic acid level.
- ▮ renal insufficiency and failure (renal acidosis). Underexcretion of metabolized acids or inability to conserve base bicarbonate results in excess acid accumulation or deficient base bicarbonate.
- ▮ diarrhea and intestinal malabsorption. Loss of sodium bicarbonate from the intestines causes the bicarbonate buffer system to shift to the acidic side.
- ▮ massive rhabdomyolysis. High quantities of organic acids added to the body with the breakdown of cells causes high anion gap acidosis.
- ▮ poisoning and drug toxicity. Common causative agents include salicylates, ethylene glycol, and methyl alcohol, which may produce acid-base imbalance.
- ▮ hypoaldosteronism and use of potassium-sparing diuretics. These conditions inhibit distal tubular secretion of acid and potassium.

Complications

If untreated, metabolic acidosis may lead to coma, arrhythmias, and cardiac arrest.

Assessment findings

The history of a patient with metabolic acidosis may point to the presence of risk factors, including associated disorders and the use of medications that contain alcohol or aspirin. Information about the patient's urine output, fluid intake, and dietary habits (including any recent fasting) may help to establish the underlying cause and severity of metabolic acidosis.

The patient's history (obtained from a family member, if necessary) also may reveal central nervous system symptoms, such as changes in level of consciousness (LOC), ranging from lethargy, drowsiness, and confusion, to stupor and coma.

Inspection findings may include Kussmaul's respirations (as the lungs attempt to compensate by “blowing off” carbon dioxide). Underlying diabetes mellitus can cause a fruity breath odor from catabolism of fats and excretion of accumulated acetone through the lungs.

PATHOPHYSIOLOGY

Measuring the anion gap

The anion gap is the difference between serum cation (sodium) and serum anion (chloride and bicarbonate) concentrations. The gap is measured by determining the cation and anion levels and then subtracting the anion from the cation level. The process begins with normal concentration values: sodium, 140 mEq/L; chloride, 104 mEq/L; and bicarbonate, 24 mEq/L.

The anion gap between *measured* cations (actually sodium alone) and *measured* anions is about 12 mEq/L (or 140 minus 128).

Concentrations of potassium, calcium, and magnesium (*unmeasured* cations), or proteins, phosphate, sulfate, and organic acids (*unmeasured* anions) aren't needed to measure the anion gap. When added together, the concentration of unmeasured cations is approximately 11 mEq/L; of unmeasured anions, about 23 mEq/L. Thus, the normal anion gap between unmeasured cations and anions is about 12 mEq/L (23 minus 11) plus or minus 2 mEq/L for normal variation.

An anion gap greater than 14 mEq/L indicates metabolic acidosis. It may result from the accumulation of excess organic acids (which are produced faster than they can be metabolized, as in ketoacidosis or lactic acidosis) or from renal insufficiency (because acids aren't excreted sufficiently). In other types of metabolic acidosis (for example, GI or renal loss of bicarbonate), the anion gap may be normal.

Palpation may reveal cold and clammy skin. As acidosis grows more severe, the skin feels warm and dry, indicating ensuing shock. Auscultation may reveal hypotension and arrhythmias. Neuromuscular assessment may reveal diminished muscle tone and deep tendon reflexes.

Diagnostic tests

Arterial blood gas analysis reveals a pH less than 7.35 to confirm metabolic acidosis, decreased partial pressure of carbon dioxide as part of the compensatory mechanism, and bicarbonate levels less than 24 mEq/L in acute metabolic acidosis.

Urine pH is 4.5 in the absence of renal disease.

Serum potassium levels are usually elevated, as hydrogen ions move into the cells and potassium moves out of the cells to maintain electroneutrality.

Blood glucose levels increase in diabetes.

Serum ketone body levels increase in diabetes mellitus.

Plasma lactic acid levels are elevated in lactic acidosis.

Anion gap values more than 14 mEq/L indicate metabolic acidosis. These values result from increased acid production or renal insufficiency. (See [Measuring the anion gap.](#))

Treatment

For acute metabolic acidosis, treatment may include I.V.administration of sodium bicarbonate (when arterial pH is less than 7.2) to neutralize blood acidity. For chronic metabolic acidosis, oral bicarbonate may be given. Other treatment measures include careful evaluation and correction of electrolyte imbalances and, ultimately, correction of the underlying cause. For example, diabetic ketoacidosis requires insulin administration and fluid replacement.

Mechanical ventilation may be required to ensure adequate respiratory compensation.

Nursing diagnoses

u Altered oral mucous membrane u Altered thought processes u Anxiety u Fear u Ineffective breathing pattern u Knowledge deficit u Risk for injury

Key outcomes

- u The patient will maintain ventilation within 5 breaths of baseline.
- u The patient will maintain a patent airway.
- u The patient's mucous membranes will remain intact.
- u The patient won't develop complications.
- u The patient will remain alert and oriented to his environment.

Nursing interventions

- u Keep sodium bicarbonate ampules handy for emergency administration. Frequently monitor the patient's vital signs, laboratory results, and LOC because changes can occur rapidly.
- u Assess respiratory functioning. Position the patient to facilitate chest expansion; turn the stuporous patient frequently.
- u In diabetic acidosis, watch for secondary changes due to hypovolemia, such as decreasing blood pressure.
- u Record the patient's intake and output accurately to monitor renal function. Watch for signs of excessive serum potassium, including weakness, flaccid paralysis, and arrhythmias, possibly leading to cardiac arrest. After treatment, check for overcorrection of hypokalemia.
- u Orient the patient frequently as needed. Reduce unnecessary environmental stimuli. Ensure a safe environment for the patient who's confused. Keep the patient's bed in the lowest position with the side rails raised.
- u Provide good oral hygiene. Use sodium bicarbonate washes to neutralize mouth acids, and lubricate the patient's lips with lemon-glycerin swabs.

Patient teaching

- u To prevent diabetic ketoacidosis, teach the patient with diabetes how to routinely test blood glucose levels or, if otherwise prescribed, how to test urine for glucose and acetone. Encourage strict adherence to insulin or oral hypoglycemic therapy, and reinforce the need to follow the prescribed dietary therapy.
- u As needed, teach the patient and family members about prescribed medications, including their mechanism of action, dosage, and possible adverse effects. Provide verbal and written instructions.

METABOLIC ALKALOSIS

Metabolic alkalosis is always secondary to an underlying cause and is marked by decreased amounts of acid or increased amounts of base bicarbonate. It's usually associated with hypocalcemia and hypokalemia, which may account for signs and symptoms. With early diagnosis and prompt treatment, the prognosis is good. Untreated metabolic alkalosis may be fatal.

Causes

Metabolic alkalosis results from the loss of acid or the increase of base.

Causes of acid loss include vomiting, nasogastric (NG) tube drainage or lavage without adequate electrolyte replacement, fistulas, and the use of steroids and certain diuretics (furosemide, thiazides, and ethacrynic acid). Hyperadrenocorticism is another cause of severe acid loss. Cushing's disease, primary hyperaldosteronism, and Bartter's syndrome all lead to sodium retention and chloride and urinary loss of potassium and hydrogen.

Excessive retention of base can result from excessive intake of bicarbonate of soda or other antacids (usually for treatment of gastritis or peptic ulcer), excessive intake of absorbable alkali (as in milk-alkali syndrome, often seen in patients with peptic ulcers), administration of excessive amounts of I.V. fluids with high concentrations of bicarbonate or lactate, massive blood transfusions, or respiratory insufficiency.

Complications

Untreated metabolic alkalosis may result in coma, atrioventricular arrhythmias, and death.

Assessment findings

The patient's history (obtained from a family member, if necessary) may disclose risk factors such as excessive ingestion of alkali antacids. The history may include extracellular fluid (ECF) volume depletion, which is frequently associated with conditions leading to metabolic alkalosis (for example, vomiting or NG tube suctioning). The patient or a family member may report irritability, belligerence, and paresthesia.

Inspection may reveal tetany if serum calcium levels are borderline or low. The rate and depth of the patient's respirations may be decreased as a compensatory mechanism; however, this mechanism is limited because of the development of hypoxemia, which stimulates ventilation.

Assessment of the patient's level of consciousness (LOC) may reveal apathy, confusion, seizures, stupor, or coma if alkalosis is severe. Neuromuscular assessment may disclose hyperactive reflexes and muscle weakness if serum potassium is markedly low. Auscultation may reveal cardiac arrhythmias occurring with hypokalemia.

Diagnostic tests

Arterial blood gas analysis may reveal a blood pH over 7.45 and a bicarbonate level over 29 mEq/L in metabolic alkalosis. A partial pressure of carbon dioxide over 45 mm Hg indicates attempts at respiratory compensation.

Serum electrolyte studies usually show low potassium, calcium, and chloride levels in metabolic alkalosis.

Electrocardiogram (ECG) findings disclose a low T wave merging with a P wave and atrial or sinus tachycardia.

Treatment

Correcting the underlying cause of metabolic alkalosis is the goal of treatment. Mild metabolic alkalosis generally requires no treatment. Rarely, therapy for severe alkalosis includes cautious I.V. administration of ammonium chloride to release hydrogen chloride and restore ECF concentration and chloride levels. Potassium chloride and normal saline solution (except with heart failure) are usually sufficient to replace losses from gastric drainage.

Electrolyte replacement with potassium chloride and discontinuing diuretics correct metabolic alkalosis resulting from potent diuretic therapy.

Nursing diagnoses

u Altered thought processes u Decreased cardiac output u Ineffective breathing pattern u Knowledge deficit u Risk for injury

Key outcomes

- u The patient will maintain cardiac output.
- u The patient will maintain adequate ventilation.
- u The patient will remain alert and oriented to his environment.
- u The patient and family members will express an understanding of the disorder and treatment regimen.

Nursing interventions

- u Structure the plan of care around cautious I.V. therapy, keen observation, and strict monitoring of the patient's status.
- u Dilute potassium when giving the patient I.V. solutions containing potassium salts. Monitor the infusion rate to prevent damage to blood vessels; use an I.V. infusion pump. Watch for signs of phlebitis.

When administering ammonium chloride 0.9% I.V., limit the infusion rate to 1 L/4 hours; faster administration may cause hemolysis of red blood cells. Avoid overdosage, which may cause overcorrection of metabolic acidosis. Don't give ammonium chloride to a patient with signs of hepatic or renal disease.

- u Monitor the patient's laboratory values, including pH, serum bicarbonate, serum potassium, and serum calcium. Notify the doctor if you detect significant changes or poor response to treatment.
- u Monitor the ECG for arrhythmias.
- u Watch closely for signs of muscle weakness, tetany, or decreased activity. Monitor the patient's vital signs frequently, and record intake and output to evaluate respiratory, fluid, and electrolyte status. Remember, respiratory rate usually decreases in an effort to compensate for alkalosis. Tachycardia may indicate electrolyte imbalance, especially hypokalemia.
- u Observe seizure precautions, and provide a safe environment for the patient with altered thought processes. Assess LOC frequently, and orient the patient as needed.
- u Irrigate the patient's NG tube with normal saline solution instead of plain water to prevent loss of gastric electrolytes. Monitor I.V. fluid concentrations of bicarbonate or lactate.

Patient teaching

- u To prevent metabolic alkalosis, warn patients against overusing alkaline agents.
- u Teach patients with ulcers to recognize signs of milk-alkali syndrome, including a distaste for milk, anorexia, weakness, and lethargy.
- u If potassium-wasting diuretics or potassium chloride supplements are prescribed, make sure the patient understands the medication regimen, including the purpose, dosage, and possible adverse effects.

PHOSPHORUS IMBALANCE

Phosphorus, the primary intracellular anion, is critical for normal cellular functioning. It's mainly found in inorganic combination with calcium in teeth and bones.

Phosphorus has a variety of important functions, such as formation of energy-storing substances (adenosine triphosphate) and support to bones and teeth. It also plays a role in utilization of B vitamins, acid-base homeostasis, nerve and muscle activity, cell division, and metabolism of carbohydrates, proteins, and fats.

Renal tubular reabsorption of phosphate is inversely regulated by calcium levels—an increase in phosphorus causes a decrease in calcium. An imbalance causes hypophosphatemia or hyperphosphatemia.

The incidence of *hypophosphatemia* varies with the underlying cause. *Hyperphosphatemia* is most common in children, who tend to consume more phosphorus-rich foods and beverages than adults do, and in children and adults with renal insufficiency.

Causes

Rarely, mild hypophosphatemia results from decreased dietary intake. When combined with overuse of phosphate-binding antacids, hypophosphatemia may become severe. Decreased absorption due to such conditions as vitamin D deficiency, malabsorption syndromes, or diarrhea may also cause this condition.

More commonly, hypophosphatemia stems from respiratory alkalosis. (Prolonged, intense hyperventilation can cause severe hypophosphatemia.) Also, increased urinary excretion associated with such conditions as hyperparathyroidism, aldosteronism, renal tubular defects, and administration of mineralocorticoids, glucocorticoids, or diuretics may lead to hypophosphatemia.

Other important causes include the use of total parenteral nutrition with inadequate phosphate content, diabetic ketoacidosis, chronic alcoholism, and alcohol withdrawal, which may lead to severe hypophosphatemia.

Hyperphosphatemia most commonly results from renal failure with decreased renal phosphorus excretion. It may also stem from overuse of laxatives with phosphates or phosphate enemas, excessive administration of phosphate supplements, and vitamin D excess with increased GI absorption.

Hyperthyroidism may be associated with hyperphosphatemia. Conditions that result in cellular destruction, such as malignant tumors (especially when treated with chemotherapy), cause phosphorus to shift out of the cell and accumulate in extracellular fluid. Respiratory acidosis may also cause such a shift.

Complications

Possible complications of hypophosphatemia include heart failure, shock, and arrhythmias. Rhabdomyolysis (destruction of striated muscle), seizures, and coma may also occur. Hypophosphatemia may increase susceptibility to infection.

Hyperphosphatemia can result in soft-tissue calcifications and complications resulting from hypocalcemia.

Assessment findings

A patient with chronic hypophosphatemia may have a history of anorexia, memory loss, muscle and bone pain, and fractures. With acute hypophosphatemia, the patient may complain of chest pain, muscle pain, apprehension, and paresthesia.

On inspection, you may detect a tremor and weakness in the patient's speaking voice and hand grasp. Depending on the severity of hypophosphatemia, you may note confusion, seizures, and coma. You also may detect bruises and bleeding due to platelet dysfunction.

A patient with hyperphosphatemia usually remains asymptomatic unless his condition results in hypocalcemia; then his chief complaint may be tetany. The patient may describe tingling sensations in the fingertips and around the mouth. He also may complain of muscle cramps.

If the patient has soft-tissue calcifications, inspection may reveal oliguria, conjunctivitis, and papular eruptions. Auscultation may reveal an irregular heart rate.

Diagnostic tests

Serum phosphorus values less than 1.7 mEq/L or 2.5 mg/dl confirm hypophosphatemia; results that are more than 2.6 mEq/L or 4.5 mg/dl confirm hyperphosphatemia.

Urine phosphorus values greater than 1.3 g/24 hours support hypophosphatemia; values under 0.9g/24 hours support hyperphosphatemia.

Serum calcium values less than 9 mg/dl support the diagnosis of hyperphosphatemia.

Treatment

The goal of treatment is to correct the underlying cause of phosphorus imbalance. In the meantime, management of hypophosphatemia consists of phosphorus replacement, with a high phosphorus diet and oral administration of phosphate salt tablets or capsules. Severe hypophosphatemia requires I.V.infusion of potassium phosphate. I.V. supplements are also required when the GI tract can't be used to administer supplements.

Hyperphosphatemia is commonly treated with aluminum, magnesium, or calcium gels or antacids, which bind with phosphorus in the intestine and increase its elimination. Reduced phosphorus in-take may be used in conjunction with these phosphorus-binding antacids. Severe hyperphosphatemia may require peritoneal dialysis or hemodialysis to lower the serum phosphorus level.

Nursing diagnoses

- u Anxiety
- u Impaired gas exchange
- u Knowledge deficit
- u Risk for injury

Key outcomes

- u The patient will maintain a patent airway.
- u The patient will maintain adequate ventilation.
- u The patient's vital signs will remain stable.
- u The patient will express feelings of comfort.
- u The patient will avoid complications.

Nursing interventions

- u Carefully monitor serum electrolyte, calcium, magnesium, and phosphorus levels. Report any changes immediately. Monitor patients at risk for phosphorus imbalance.

For hypophosphatemia:

- u Record the patient's fluid intake and output accurately.
- u Administer I.V. potassium phosphate slowly to prevent overcorrection to hyperphosphatemia. Administer the infusion at a rate no greater than 10 mEq/hour. Observe for signs of infiltration; potassium phosphate can cause tissue sloughing and necrosis.
- u Assess the patient's renal function, and be alert for signs of hypocalcemia such as tetany when giving phosphate supplements. If phosphate salt tablets cause nausea, use capsules instead.
- u Observe safety precautions: Keep the patient's bed in its lowest position, with the wheels locked and all four side rails raised. If seizures are possible, pad the side rails and keep an oral airway at the patient's bedside.
- u Monitor the rate and depth of respirations. Report such signs of hypoxia as confusion and cyanosis.
- u Frequently assess the patient's level of consciousness and neurologic status. Orient the patient as needed.
- u Administer medication for bone pain as ordered. Assist the patient with ambulation and activities of daily living.

For hyperphosphatemia:

- u Monitor the patient's intake and output. If urine output falls below 25 ml/hour or 600 ml/day, notify the doctor immediately; decreased output can seriously affect renal clearance of excess serum phosphorus.
- u Watch for signs of hypocalcemia, such as muscle twitching and tetany, which often accompany hyperphosphatemia.
- u Obtain a dietary consultation if the condition results from chronic renal insufficiency.

Patient teaching

For patients with hypophosphatemia:

- u To prevent recurrence, advise the patient to follow a high-phosphorus diet containing milk and milk products, kidney, liver, turkey, dried fruit, seeds, eggs, nuts, and whole grains.
- u Provide verbal and written instructions for the patient taking prescribed oral phosphate supplements.

For patients with hyperphosphatemia:

- u Make sure the patient and family understand the medication regimen, including possible adverse effects and dosage of prescribed phosphate binders.
- u Encourage the patient to avoid foods with high phosphorus content. Review foods with low phosphorus content, such as vegetables.
- u Stress the importance of avoiding nonprescription preparations containing phosphorus or phosphate, such as laxatives and enemas.

POTASSIUM IMBALANCE

Potassium—a cation and the dominant cellular electrolyte—facilitates contraction of both skeletal and smooth muscles, including myocardial contraction. It figures prominently in nerve impulse conduction, acid-base balance, enzyme action, and cell membrane function. Because serum potassium level has such a narrow range (3.5 to 5 mEq/L), a slight deviation in either direction can produce profound consequences.

Causes

Hypokalemia rarely results from a dietary deficiency because many foods contain potassium. Instead, potassium loss results from:

- u excessive GI losses, such as vomiting, gastric suction, diarrhea, villous adenoma, and laxative abuse
- u chronic renal disease, with tubular potassium wasting
- u certain drugs, especially potassium-wasting diuretics, steroids, and certain sodium-containing antibiotics (carbenicillin)
- u alkalosis or insulin effect, which causes potassium shifting into cells without depletion of total body potassium
- u prolonged potassium-free I.V. therapy
- u hyperglycemia, causing osmotic diuresis and glycosuria
- u Cushing's syndrome, primary hyperaldosteronism, excessive ingestion of licorice, and severe serum magnesium deficiency.

Hyperkalemia usually results from reduced excretion by the kidneys. This may be due to acute or severe chronic renal failure, oliguria due to shock or severe dehydration, or the use of potassium-sparing diuretics such as triamterene by patients with renal disease. Inadequate potassium excretion may also be due to hyperaldosteronism or Addison's disease.

Hyperkalemia may also result from failure to excrete excessive amounts of potassium infused I.V. or administered orally. Another cause is massive release of

intracellular potassium, such as can occur with burns, crushing injuries, severe infection, or acidosis.

Complications

Potassium imbalances may result in muscle weakness and flaccid paralysis and can lead to cardiac arrest.

Assessment findings

The patient's history and physical examination may reveal cardiovascular irregularities manifested by dizziness, postural hypotension, and arrhythmias. (See [Clinical features of potassium imbalance.](#))

GI complaints may include nausea and vomiting, anorexia, abdominal distention, constipation, paralytic ileus, and decreased peristalsis (with hypokalemia) or nausea, diarrhea, and abdominal cramps (with hyperkalemia).

The patient may also experience neuromuscular symptoms, such as weakness and hyporeflexia (with hypokalemia); skeletal muscle weakness, numbness, and tingling (with hyperkalemia); and flaccid paralysis or respiratory paralysis (with both imbalances).

Diagnostic tests

Serum potassium levels allow definitive diagnosis of a potassium abnormality. In hypokalemia, potassium levels are less than 3.5 mEq/L. In hyperkalemia, levels are more than 5 mEq/L.

Additional tests may be necessary to determine the underlying cause of the imbalance.

Treatment

Hypokalemia treatment should involve increased dietary intake of potassium or oral supplements with potassium salts. Potassium chloride is the preferred choice. Edematous patients with diuretic-induced hypokalemia should receive a potassium-sparing diuretic such as spironolactone.

Patients with GI potassium loss or severe potassium depletion require I.V. potassium replacement therapy. If hypocalcemia is also present, treatment should include calcium replacement. (See [Administering I.V. potassium safely.](#))

For patients with hyperkalemia, treatment consists of withholding potassium and administering a cation exchange resin orally or by enema. Sodium polystyrene sulfonate (Kayexalate) with 70% sorbitol exchanges sodium ions for potassium ions in the intestine.

In an emergency, rapid infusion of 10% calcium gluconate decreases myocardial irritability and temporarily prevents cardiac arrest but doesn't correct serum potassium excess; it's also contraindicated in patients receiving digoxin.

Also as an emergency measure, sodium bicarbonate I.V. increases pH and causes potassium to shift back into the cells. Insulin and 10% to 50% glucose I.V. also move potassium back into cells. Infusions should be followed by dextrose 5% in water because infusion of 10% to 15% glucose stimulates secretion of endogenous insulin. Hemodialysis or peritoneal dialysis also helps remove excess potassium, but these are slow techniques.

Nursing diagnoses

u Constipation u Decreased cardiac output u Diarrhea u Fluid volume deficit u Knowledge deficit u Risk for injury

Key outcomes

- u The patient will maintain adequate cardiac output.
- u The patient's vital signs will remain stable.
- u The patient's bowel movements will return to normal.
- u The patient's intake will equal his output.
- u The patient and family members will express an understanding of the disorder and treatment regimen.

Nursing interventions

For hypokalemia:

- u Frequently monitor serum potassium and other electrolyte levels during potassium replacement therapy to avoid overcorrection of hyperkalemia.
- u Assess intake and output carefully. Remember, the kidneys excrete 80% to 90% of ingested potassium. Never give supplementary potassium to a patient whose urine output is below 600 ml/day. Also, measure GI loss from suctioning or vomiting.
- u Because of the risk of potassium toxicity, administer I.V. potassium slowly and cautiously to prevent cardiac arrhythmias and vein irritation.
- u If the patient is taking a liquid oral potassium supplement, have him sip it slowly to prevent GI irritation. Give the supplement during or after meals with a full glass of water or fruit juice.
- u Carefully monitor patients receiving digoxin because hypokalemia enhances the action of digoxin Assess for signs of digitalis toxicity (anorexia, nausea, vomiting, blurred vision, and arrhythmias).
- u Monitor cardiac rhythm, and report any irregularities immediately.
- u Implement safety measures for the patient with muscle weakness or postural hypotension.

Clinical features of potassium imbalance

DYSFUNCTION	HYPOKALEMIA	HYPERKALEMIA
Cardiovascular	Dizziness, hypotension, arrhythmias, electrocardiogram (ECG) changes, (flattened T waves, elevated U waves, depressed ST segment), cardiac arrest (with serum potassium levels less than 2.5 mEq/L)	Tachycardia and altered bradycardia, ECG changes (tented and elevated T waves, widened QRS, prolonged PR interval, flattened or absent P waves, depressed ST segment), cardiac arrest (with levels greater than 7 mEq/L)
Gastrointestinal	Nausea and vomiting, anorexia, diarrhea, abdominal distention, paralytic ileus or decreased peristalsis	Nausea, diarrhea, abdominal cramps
Musculoskeletal	Muscle weakness and fatigue, leg cramps	Muscle weakness, flaccid paralysis
Genitourinary	Polyuria	Oliguria, anuria
Central nervous system	Malaise, irritability, confusion, mental depression, speech changes, decreased reflexes, respiration paralysis	Hyperreflexia progressing to weakness, numbness, tingling, and flaccid paralysis
Acid-base balance	Metabolic alkalosis	Metabolic acidosis

u Assess for abdominal distention, decreased bowel sounds, and constipation.

For hyperkalemia:

- u As in hypokalemia, frequently monitor serum potassium and other electrolyte levels, and carefully record intake and output.
- u Administer sodium polystyrene sulfonate orally, or rectally by retention enema. (Encourage the patient to retain the enema for at least 30 to 60 minutes.) Watch for signs of hypokalemia with prolonged use.
- u Assess for clinical effects of hypoglycemia (muscle weakness, syncope, hunger, and diaphoresis) with repeated insulin and glucose treatment.
- u Monitor and report cardiac arrhythmias.
- u Provide sufficient calories to prevent tissue breakdown and release of potassium into extracellular fluid.
- u Assess GI functioning for abdominal distention, intestinal cramping, and diarrhea.
- u Implement safety measures for the patient with muscle weakness.

ASSESSMENT TIP Watch for signs of hyperkalemia in predisposed patients, especially those with poor urine output or those receiving potassium supplements by mouth or I.V. Also, before giving a blood transfusion, check to see when the blood was donated; older blood cell hemolysis releases potassium. Infuse only fresh blood for patients with average to high serum potassium levels.

Patient teaching

- u To prevent hypokalemia, instruct patients (especially those taking diuretics) to include potassium-rich foods in their diets. Such foods include oranges, bananas, tomatoes, milk, dried fruit, apricots, peanuts, and dark green, leafy vegetables.
- u Emphasize the importance of taking potassium supplements as prescribed, particularly if the patient is also taking digoxin or diuretics. If appropriate, teach the patient to recognize and report signs of digitalis toxicity such as pulse irregularities. Demonstrate the proper technique for assessing the patient's pulse.
- u Make sure the patient can recognize signs of hypokalemia and hyperkalemia, including weakness and pulse irregularities. Tell him to report them to the doctor.
- u To prevent hyperkalemia, teach patients who use salt substitutes containing potassium to discontinue them if urine output decreases.

SODIUM IMBALANCE

Sodium is the major cation (90%) in extracellular fluid (ECF). It's the main factor responsible for ECF concentration. Increases or decreases in ECF sodium concentrations greatly affect ECF volume and distribution. Sodium controls the distribution of water throughout the body and regulates ECF volume. It also plays an important role in the transmission of nerve impulses and muscle contraction.

Hyponatremia is an excess of body water relative to sodium; it isn't synonymous with sodium depletion. Sodium loss is just one state in which hyponatremia can occur. Hypernatremia is a deficit of body water relative to sodium. Thirst seems to be the major defense mechanism against hypernatremia.

The body requires only 2 to 4 g of sodium per day, but most Americans consume 6 to 10 g per day (mostly sodium chloride, as table salt) and excrete excess sodium through the kidneys and skin. Under the influence of antidiuretic hormone (ADH) and aldosterone, the kidneys primarily regulate ECF sodium balance.

Causes

Hyponatremia usually results from defective urine dilution, caused by either an excessive loss of sodium or an excessive gain of water. Specific causes of hyponatremia include:

- u excessive GI loss of water and electrolytes due to vomiting, suctioning, fistulas, or diarrhea; excessive perspiration; or fever. When such losses decrease circulating fluid volume, increased secretion of ADH promotes maximum water reabsorption, which further dilutes serum sodium. Combined with too much free water intake, these factors are especially likely to cause hyponatremia.
- u diuretic therapy, most commonly thiazides
- u excessive drinking of water (psychogenic polydipsia); infusion of I.V. dextrose in water without other solutes, particularly during stress
- u endocrine disorders, such as adrenal gland insufficiency and moderate to severe hypothyroidism
- u chronic illnesses, such as cirrhosis of the liver and heart failure
- u syndrome of inappropriate antidiuretic hormone (SIADH) secretion, resulting from central nervous system disorders, such as head injury and cerebrovascular accident; nonmalignant pulmonary diseases such as tuberculosis; neoplasms with ectopic ADH production such as oat cell lung tumors; or certain drugs, such as chlorpropamide and clofibrate.

Hypernatremia results from excessive sodium intake with inadequate water intake or, most commonly, by water loss with inadequate sodium loss. It may also result from water loss alone. Specific causes of hypernatremia include:

- u severe insensible water losses that aren't replaced, such as in patients with fever, hyperventilation, or extensive burns

WARNING

Administering I.V. potassium safely

I.V. replacement of potassium is necessary only if hypokalemia is severe or if the patient can't take supplements by mouth. Carefully monitor I.V. potassium replacement to prevent or reduce toxic effects. Follow these guidelines:

- I.V. infusion concentrations generally shouldn't exceed 60 mEq/L. The infusion rate shouldn't exceed 20 mEq/hour, unless indicated. More concentrated potassium solutions may be used in severely fluid-restricted patients.
- Use volumetric devices whenever concentrations of more than 40 mEq/L are infused.
- Never administer potassium by I.V. push or bolus; it may cause cardiac arrest.
- Monitor cardiac rhythm during rapid I.V. administration of potassium to avoid cardiac toxicity from inadvertent hyperkalemia. Report any irregularities immediately.
- Monitor serum potassium levels, and evaluate signs and symptoms such as muscle weakness.
- Monitor the I.V. site for signs and symptoms of infiltration, phlebitis, or tissue necrosis.

- severe renal water losses, as in acute diabetes insipidus
- severe vomiting and diarrhea causing water loss that exceeds sodium loss; serum sodium levels increase, but overall ECF volume decreases
- excess adrenocortical hormones, as in Cushing's syndrome
- water loss with inadequate sodium loss due to diaphoresis, if the patient can't drink
- administration of high-protein feedings without adequate water supplement (due to urea diuresis)
- sodium excess, such as administration of excessive amounts of hypertonic sodium chloride infusions to obtunded patients who can't drink or inadvertent introduction of hypertonic sodium chloride solution into maternal circulation during therapeutic abortion.

Thirst is such a strong drive that severe, persistent hypernatremia only occurs in people who can't respond to thirst voluntarily, such as infants and unconscious patients. A disturbance of the thirst mechanism is rare.

Complications

States of severe hyponatremia or hypernatremia may result in seizures, coma, and permanent neurologic damage.

Clinical effects of sodium imbalance		
SYSTEM	HYPONATREMIA	HYPERNATREMIA
Central nervous system	Anxiety, headaches, muscle twitching and weakness, seizures	Fever, agitation, restlessness, seizures
Cardiovascular	Hypotension; tachycardia; with severe deficit, vasomotor collapse, thready pulse	Hypotension, tachycardia, pitting edema, excessive weight gain
GI	Nausea, vomiting, abdominal cramps	Rough, dry tongue; intense thirst
Genitourinary	Oliguria or anuria	Oliguria
Respiratory	Cyanosis with severe deficiency	Dyspnea, respiratory arrest, and death (from dramatic increase in osmotic pressure)
Cutaneous	Cold, clammy skin; decreased skin turgor	Flushed skin; dry, sticky mucous membranes

Hyponatremia may lead to cerebral edema, as decreased plasma osmolality causes water movement into cells. Increased brain cell volume, in turn, leads to neurologic symptoms.

Increased plasma osmolality associated with hypernatremia causes a water shift out of cells, possibly resulting in cerebral cell dehydration and neurologic symptoms.

Assessment findings

A patient with hyponatremia may complain initially of anorexia, nausea, abdominal cramping, headache, and exhaustion. When the serum sodium level drops further (between 120 and 125 mEq/L), neurologic assessment may reveal lethargy, confusion, twitching, and focal weakness, which, if untreated, may progress to seizures and coma.

If hyponatremia is secondary to ECF loss, the patient may complain of dizziness. Palpation may disclose dry mucous membranes, and vital sign assessment reflects orthostatic hypotension and tachycardia.

If hyponatremia is secondary to fluid gain, inspection may reveal edema; palpation may disclose fingerprint edema (with SIADH); further assessment may reveal hypertension and weight gain.

A patient with hypernatremia may complain of fatigue, restlessness, and weakness. When hypernatremia is severe, assessment of level of consciousness (LOC) may reveal disorientation, which may progress to seizures and coma.

On inspection, the hypernatremic patient may have flushed skin. Palpation may reveal a dry, swollen tongue and sticky mucous membranes. The patient may have a low-grade fever. (See [Clinical effects of sodium imbalance.](#))

Diagnostic tests

Serum sodium levels are less than 135 mEq/L with hyponatremia and greater than 145 mEq/L with hypernatremia.

Additional laboratory studies are used to determine the etiology of the imbalance and differentiate between a true deficit and an apparent deficit due to sodium shift or to hypervolemia or hypovolemia.

Treatment

When possible, patients with sodium deficits receive oral sodium supplementation. Therapy for mild hyponatremia associated with hypervolemia usually consists of restricted water intake. If fluid restriction alone fails to normalize serum sodium levels, demeclocycline or lithium, which blocks ADH action in the renal tubules, can be used to promote water excretion.

In extremely rare instances of severe symptomatic hyponatremia, when serum sodium levels fall below 110 mEq/L, treatment may include infusion of 3% or 5%

sodium chloride solution.

Treatment with an infusion of hypertonic saline solution requires careful patient monitoring in an intensive care setting for signs of circulatory overload, which is potentially fatal. (Administration of hypertonic saline solution causes water to shift out of cells, risking intravascular volume overload.) For this reason, furosemide is usually administered concurrently. The hypertonic saline solution is infused slowly, in small volumes.

If indicated, treatment must include correction of the underlying disorder; for example, hormonal therapy may be needed to treat endocrine disorders.

Primary treatment for hyponatremia associated with water deficit includes slow, oral replacement of the water deficit to stop the water loss. If the patient can't tolerate oral replacement, treatment requires I.V. administration of salt-free solutions (such as dextrose in water) to return serum sodium levels to normal, followed by infusion of half-normal saline solution to prevent hyponatremia.

ALERT Hyponatremia must be corrected slowly, over about 2 days, to avoid shifting water into brain cells, resulting in cerebral edema. Some clinicians recommend infusion of a hypotonic solution, such as 0.3% sodium chloride, to permit a more gradual lowering of serum sodium levels, reducing the risk of cerebral edema.

Other treatment measures may include restricted sodium intake for patients with sodium gain. Diuretics may be given to increase sodium loss in combination with oral or I.V. water replacement.

Nursing diagnoses

- u Altered thought processes
- u Altered tissue perfusion (cardiopulmonary)
- u Anxiety
- u Fatigue
- u Fear
- u Fluid volume deficit
- u Knowledge deficit
- u Risk for injury

Key outcomes

- u The patient will maintain adequate fluid volume.
- u The patient's laboratory values will return to normal.
- u The patient will avoid complications.
- u The patient's vital signs will remain stable.
- u The patient will remain alert and oriented to his environment.

Nursing interventions

For hyponatremia:

- u Watch for and report extremely low serum sodium and accompanying serum chloride levels. Monitor urine specific gravity and other laboratory results. Record fluid intake and output accurately, and weigh the patient daily.
- u During administration of isosmolar or hyperosmolar sodium chloride solution, watch closely for signs of hypervolemia (dyspnea, crackles, engorged neck or hand veins), and report them immediately.
- u Conserve the patient's energy through rest, planning, and setting priorities; avoid unnecessary fatigue.

For hypernatremia:

- u Monitor serum sodium levels. Notify the doctor of rapid decreases in levels because rapid correction of hypernatremia may lead to cerebral edema. Increases in serum sodium levels should also be reported because they may signal the need for additional treatment.
- u During fluid replacement therapy, observe for signs and symptoms of cerebral edema, particularly headache, lethargy, nausea, vomiting, widening pulse pressure, decreased pulse rate, and seizures.
- u Record fluid intake and output accurately, checking for body fluid loss. Weigh the patient daily.
- u Assist with oral hygiene. Lubricate the patient's lips frequently with a water-based lubricant. Provide mouthwash or gargle if the patient is alert.
- u Obtain a drug history to check for drugs that promote sodium retention.

For hyponatremia or hypernatremia:

- u Perform frequent neurologic checks. Report deteriorating LOC. Provide a safe environment for the patient with altered thought processes. If seizures are likely, pad the side rails and keep an oral airway at the bedside. Reorient the patient as needed.

Patient teaching

For patients with hyponatremia:

- u Refer the patient to a dietitian for instruction about dietary sodium intake if he's on a maintenance dosage of diuretics.
- u Teach the patient and family the rationale for fluid restriction, if prescribed. Inform the patient of ways to minimize thirst, including the use of ice chips, ice pops, or lemon drops.
- u Make sure the patient understands the medication regimen, including the drug name, action, dosage, precautions, and potential adverse effects.

For patients with hypernatremia:

- u If warranted, explain the importance of sodium restriction, and teach the patient how to plan a lowsodium diet. Refer the patient to a dietitian for additional teaching.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

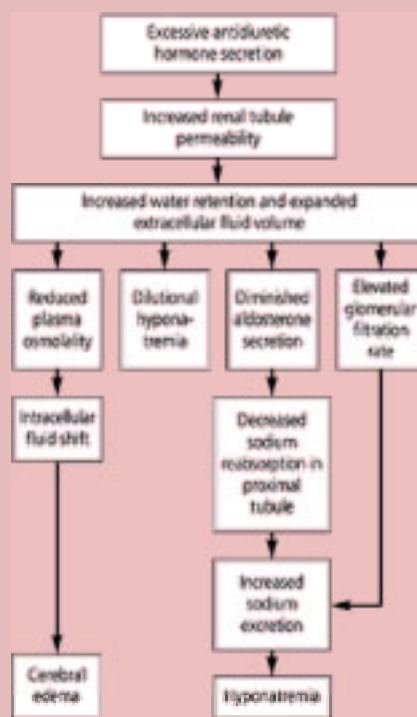

Syndrome of inappropriate antidiuretic hormone (SIADH) secretion, a potentially life-threatening condition, is marked by excessive release of antidiuretic hormone (ADH), which disturbs fluid and electrolyte balance. SIADH occurs secondary to diseases that affect the osmoreceptors (supraoptic nucleus) of the hypothalamus. The prognosis depends on the underlying disorder and the patient's response to treatment. (See [Understanding SIADH.](#))

PATHOPHYSIOLOGY

Understanding SIADH

The following flowchart shows the events that produce the syndrome of inappropriate antidiuretic hormone (SIADH) secretion.

Causes

Usually, SIADH results from oat cell carcinoma of the lung, which secretes excessive ADH or vasopressor-like substances. Other neoplastic diseases (such as pancreatic and prostatic cancers, Hodgkin's disease, and thymoma) may also trigger SIADH. Additional causes include:

- u central nervous system (CNS) disorders, including brain tumor or abscess, cerebrovascular accident, head injury, and Guillain-Barré syndrome
- u pulmonary disorders (such as pneumonia, tuberculosis, and lung abscess) and positive-pressure ventilation
- u drugs (for example, chlorpropamide, tolbutamide, vincristine, cyclophosphamide, haloperidol, carbamazepine, clofibrate, morphine, and thiazides)
- u miscellaneous conditions (such as myxedema and psychosis).

Complications

Without prompt treatment, SIADH may lead to water intoxication, cerebral edema, and severe hyponatremia, with resultant coma and death.

Assessment findings

The patient's medical and medication histories may provide a clue to the cause of SIADH. A history of cerebrovascular disease, cancer, pulmonary disease, or recent head injury is especially significant.

Most commonly, a patient with SIADH complains of anorexia, nausea, and vomiting. Despite these symptoms, the patient may report weight gain. The patient or family may also report CNS symptoms, such as lethargy, headaches, and emotional and behavioral changes.

Inspection usually fails to reveal edema because much of the free water excess is within cellular boundaries. Palpation may disclose tachycardia associated with increased fluid volume. Neurologic assessment may reveal disorientation, which may progress to seizures and coma. Examination findings may also include sluggish deep tendon reflexes and muscle weakness.

Diagnostic tests

Serum osmolality levels less than 280 mOsm/kg of water and serum sodium levels less than 123 mEq/L confirm SIADH.

Urine sodium levels more than 20 mEq/L without diuretics support the SIADH diagnosis.

Renal function tests are normal with no evidence of dehydration in SIADH.

Treatment

Treatment for a patient with SIADH is based primarily on the patient's symptoms and begins with restricted water intake (500 to 1,000 ml/day). Some patients who continue to have symptoms are given a high-salt, high-protein diet or urea supplements to enhance water excretion. Or they may receive demeclocycline or lithium to help block the renal response to ADH.

Rarely, with severe water intoxication, administration of 200 to 300 ml of 3% to 5% sodium chloride solution may be needed to raise the serum sodium level. A loop diuretic may also be prescribed to reduce the risk of heart failure after the excess fluid load and the administration of the hypertonic sodium chloride solution. When possible, treatment should include correction of the underlying cause of SIADH. If SIADH is due to cancer, success in alleviating water retention may be obtained by surgery, irradiation, or chemotherapy.

If fluid restriction is ineffective, demeclocycline may be helpful by blocking the response to ADH.

Nursing diagnoses

- u Altered thought processes
- u Anxiety
- u Fear
- u Fluid volume excess
- u Knowledge deficit
- u Risk for injury

Key outcomes

- u The patient won't develop complications.
- u The patient will remain alert and oriented to environment.
- u The patient will express an understanding of the disorder and treatment regimen.
- u The patient will maintain adequate fluid volume.
- u The patient's intake will equal his output.

Nursing interventions

- u Closely monitor and record the patient's intake and output, vital signs, and daily weight. Watch for hyponatremia.
- u Restrict fluids, and provide comfort measures for thirst, including ice chips, mouth care, lozenges, and staggered water intake.
- u Perform frequent neurologic checks, depending on the patient's status. Look for and report early changes in level of consciousness (LOC). Reduce unnecessary environmental stimuli and orient the patient as needed.
- u Provide a safe environment for the patient with an altered LOC. Take seizure precautions as needed.

- u Observe for signs and symptoms of heart failure, which may occur due to fluid overload.

Patient teaching

- u If SIADH doesn't resolve by the time of discharge, explain to the patient and family members why he *must* restrict fluid intake. Review ways to decrease the patient's discomfort from thirst (such as chewing sugar-free gum, sucking on sugar-free candy, and practicing relaxation techniques and yoga).
- u If drug therapy is prescribed, teach the patient and family about the regimen, including dosage, action, and possible adverse effects.
- u Discuss self-monitoring techniques for fluid retention, including measurement of intake and output and daily weight. Teach the patient to recognize signs and symptoms that require immediate medical intervention.

INTRODUCTION

The endocrine system consists of *glands* (specialized cell clusters) and *hormones* (chemical transmitters secreted by the glands in response to central nervous system [CNS] stimulation). Together with the CNS, the endocrine system regulates and integrates the body's metabolic activities and maintains internal homeostasis.

Hormonal regulation

The hypothalamus, the main integrative center for the endocrine and autonomic nervous systems, helps control some endocrine glands by neural and hormonal pathways. Neural pathways connect the hypothalamus to the posterior pituitary gland, or neurohypophysis. Neural stimulation of the posterior pituitary gland causes the secretion of two effector hormones: antidiuretic hormone (ADH, or vasopressin) and oxytocin.

The hypothalamus also exerts hormonal control at the anterior pituitary gland, or adenohypophysis, by releasing and inhibiting hormones and factors, which arrive through a portal system. Hypothalamic hormones stimulate the pituitary gland to release trophic hormones, such as corticotropin; thyroid-stimulating hormone (TSH); melanocyte-stimulating hormone (MSH); and gonadotropins, such as luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Hypothalamic hormones also stimulate the pituitary gland to release or inhibit effector hormones, such as growth hormone (GH) and prolactin. Secretion of trophic hormones stimulates the adrenal cortex, thyroid gland, and gonads.

In a patient with a possible endocrine disorder, this complex hormonal sequence requires careful assessment to identify the dysfunction, which may result from defects in the gland; defects of releasing, trophic, or effector hormones; or defects of the target tissue. Hyperthyroidism, for example, may result from excessive thyrotropin-releasing hormone, TSH, or thyroid hormones.

In addition to hormonal and neural controls, a negative feedback system regulates the endocrine system. (See [Feedback mechanism of the endocrine system](#).) The feedback mechanism may be simple or complex. Simple feedback occurs when the level of one substance regulates secretion of a hormone. For example, a low serum calcium level stimulates parathyroid hormone (PTH) secretion from the parathyroid glands; a high serum calcium level inhibits PTH.

Complex feedback occurs through the hypothalamic-pituitary-target organ axis. For example, secretion of the hypothalamic corticotropin-releasing hormone (CRH) releases pituitary corticotropin, which, in turn, stimulates adrenal cortisol secretion. Subsequently, an increase in serum cortisol levels inhibits corticotropin by decreasing CRH secretion. Corticosteroid therapy disrupts the hypothalamic-pituitary-adrenal (HPA) axis by suppressing the hypothalamic-pituitary secretion mechanism. Because abrupt withdrawal of steroids doesn't allow time for recovery of the HPA axis to stimulate cortisol secretion, it can induce life-threatening adrenal crisis.

Hormonal effects

The *posterior pituitary gland* secretes oxytocin and ADH. Oxytocin stimulates contraction of the uterus and is responsible for the milk let-down reflex in lactating women. ADH controls the concentration of body fluids by altering the permeability of the distal convoluted tubules and collecting ducts of the kidneys to conserve water. ADH secretion depends on plasma osmolality as monitored by hypothalamic neurons. Hypovolemia and hypotension are the most powerful stimulators of ADH release. Other stimulators include pain, stress, trauma, nausea, morphine, tranquilizers, certain anesthetics, and positive-pressure breathing.

The *anterior pituitary gland* secretes prolactin, which stimulates milk secretion, and GH. GH affects most body tissues, triggering growth by increasing protein synthesis and fat mobilization and decreasing carbohydrate use.

The *thyroid gland* secretes the iodinated hormones thyroxine (T₄) and triiodothyronine (T₃). Thyroid hormones are necessary for normal growth and development and act on many tissues to increase metabolic activity and protein synthesis.

The *parathyroid glands* secrete PTH, which regulates calcium and phosphate metabolism. PTH elevates serum calcium levels by stimulating resorption of calcium and phosphate from bone, reabsorption of calcium and excretion of phosphate by the kidneys, and—by combined action with vitamin D—absorption of calcium and phosphate from the GI tract. Calcitonin, another hormone secreted by the thyroid gland, affects calcium metabolism, but its precise role in humans is unknown.

The *pancreas* produces glucagon from the alpha cells and insulin from the beta cells. Glucagon, the hormone of the fasting state, releases stored glucose from the liver to increase blood glucose levels. Insulin, the hormone of the postprandial state, facilitates glucose transport into the cells, promotes glucose storage, stimulates protein synthesis, and enhances free fatty acid uptake and storage.

Feedback mechanism of the endocrine system

The hypothalamus receives regulatory information (feedback) from its own circulating hormones (simple loop) and also from target glands (complex loop).

The *adrenal cortex* secretes mineralocorticoids, glucocorticoids, and sex steroid hormones (androgens). Aldosterone, a mineralocorticoid, regulates the reabsorption of sodium and the excretion of potassium by the kidneys. Aldosterone is affected by corticotropin and is regulated by angiotensin II, which is regulated by renin. Together, aldosterone, angiotensin II, and renin may be implicated in the pathogenesis of hypertension.

Cortisol, a glucocorticoid, stimulates gluconeogenesis, increases protein breakdown and free fatty acid mobilization, suppresses the immune response, and provides for an appropriate response to stress.

The *adrenal medulla* is an aggregate of nervous tissue that produces the catecholamines epinephrine and norepinephrine, both of which cause vasoconstriction. In addition, epinephrine causes the fight-or-flight response: Dilation of bronchioles and increased blood pressure, blood glucose level, and heart rate.

The *testes* synthesize and secrete testosterone in response to gonadotropic hormones, especially LH, from the anterior pituitary gland; spermatogenesis occurs in response to FSH. The *ovaries* produce sex steroid hormones (primarily estrogen and progesterone) in response to anterior pituitary trophic hormones.

Endocrine disorders

The most common endocrine disorders include hypofunction (hormone deficiency), hyperfunction (hormone overproduction), inflammation, and tumor. The source of hypofunction and hyperfunction may be the hypothalamus, the pituitary effector glands, or the target gland. Inflammation may be acute or subacute, as in thyroiditis, but is usually chronic, often resulting in glandular hypofunction. Tumors can occur within the gland—as in thyroid carcinoma or pheochromocytoma (excessive catecholamines)—or in other areas, resulting in ectopic hormone production. Certain lung tumors, for example, secrete ADH or PTH.

Assessment

A thorough assessment can help to identify an endocrine disorder. The patient with such a disorder commonly reports fatigue, weakness, weight changes, mental status changes, polyuria, polydipsia, and abnormalities of sexual maturity and function. Careful questioning may identify insidious, vague symptoms that might otherwise go unreported. A thorough family history can uncover a familial tendency toward endocrine disorders.

CULTURAL TIP Ask patients about cultural background and hereditary to ensure that your findings aren't due to cultural variance. For example, a person of short stature may have a growth hormone deficiency, but members of Asian descent commonly have short stature with no related disorder.

Your physical examination should include a total body evaluation and complete neurologic assessment. Begin with the patient's vital signs, height, and weight. Compare these measurements with normal expected ones and the patient's baseline measurements, if available. Then, to obtain the most objective findings, inspect, palpate, and auscultate the patient.

Inspection

Systematically note the patient's overall appearance and mental and emotional status. Consider such factors as overall affect, speech, level of consciousness, orientation, appropriateness of behavior, grooming and dress, and activity level. Observe general body development, posture, body build, proportionality of body parts, and distribution of body fat and hair.

Assess overall skin color. Inspect the skin and mucous membranes for any lesions or areas of increased, decreased, or absent pigmentation. Assess the face for erythematous areas. Note facial expression, shape and symmetry of the eyes, and the presence of eyeball protrusion, incomplete lid closure, or periorbital edema. Inspect the tongue for color, size, lesions, tremor, and positioning. Stand in front of the patient and inspect the neck area for symmetry. Then check the neck while the patient holds it straight, slightly extends it, and then swallows water. Also remember to check for tracheal symmetry.

Evaluate the overall size, shape, and symmetry of the chest, noting any deformities, especially around the nipples. Inspect the external genitalia for normal development. Inspect the arms and legs for tremors, muscle development, symmetry, color, and hair distribution. Assess muscle strength. Examine the feet, noting size, deformities, lesions, marks from shoes and socks, maceration, dryness, or fissures.

Palpation

The thyroid gland and the testes are the only endocrine glands accessible to palpation. In many patients, the thyroid gland isn't palpable, but if it is, it should be smooth, finely lobulated, nontender, and either soft or firm. The gland's sections also should be palpable. The testes are palpable within the scrotal sac and are usually small, round, and firm.

Auscultation

Auscultate the thyroid gland to identify systolic bruits. These are caused by vibrations produced by accelerated blood flow through the thyroid arteries.

Diagnostic tests

The results of various diagnostic tests can be used to suggest, confirm, or rule out an endocrine disorder. Endocrine function can be tested by direct, indirect, provocative, and radiographic studies.

Direct testing, the most common method of measuring endocrine function, involves measuring the hormone levels in blood or urine. Because the body contains only minute quantities of hormones, special techniques may be needed to obtain accurate measurements.

Common endocrine blood tests include:

- u cortisol measurement to evaluate adrenocortical function
- u catecholamine measurement to assess adrenal medulla function
- u PTH measurement to evaluate parathyroid function
- u GH radioimmunoassay to evaluate GH oversecretion
- u T₄ radioimmunoassay to evaluate thyroid function and monitor iodine or antithyroid therapy
- u T₃ radioimmunoassay to detect hyperthyroidism if T₄ levels are normal
- u FSH and LH measurements to distinguish a primary gonadal problem from pituitary insufficiency.

Common endocrine urine studies include:

- u 17-ketosteroid test to evaluate adrenocortical and gonadal function
- u 17-hydroxycorticosteroid test to evaluate adrenal function
- u free cortisol test
- u 24-hour urine test.

Indirect testing is used to measure the substance a particular hormone controls, not the hormone itself. Examples include:

- u oral glucose tolerance test to detect impaired glucose tolerance and hypoglycemia
- u calcium measurement to detect bone and parathyroid disorders
- u phosphorus test to detect parathyroid disorders and renal failure
- u glycosylated hemoglobin test to monitor the degree of glucose control in diabetes mellitus over 3 months.

Provocative testing helps to determine an endocrine gland's reserve function when other tests show borderline hormone levels, but it can't pinpoint the site of the abnormality. These tests work on the principle that an underactive gland is stimulated and an overactive gland is suppressed, depending on the patient's suspected disorder. Examples include:

- u insulin-induced hypoglycemia test to detect hypopituitarism
- u TSH test to detect primary hypothyroidism
- u radiographic studies to evaluate the endocrine system, including X-rays, computed tomography scans, magnetic resonance imaging, and nuclear imaging.

Pituitary disorders

Two disorders of the pituitary gland—hypopituitarism and hyperpituitarism—cause abnormal growth. A third pituitary disorder—diabetes insipidus—causes excessive urine output.

DIABETES INSIPIDUS

A deficiency of vasopressin (also called antidiuretic hormone) causes diabetes insipidus, which is a water metabolism disorder characterized by excessive fluid intake and hypotonic polyuria. The disorder may start in childhood or early adulthood (median age of onset is 21) and is more common in men than in women. Incidence is slightly higher today than in the past.

In uncomplicated diabetes insipidus, with adequate water replacement, the prognosis is good and patients usually lead normal lives. However, in cases complicated by an underlying disorder, such as cancer, the prognosis varies.

Causes and pathophysiology

The most common cause of diabetes insipidus is failure of vasopressin secretion in response to normal physiologic stimuli (pituitary or neurogenic diabetes insipidus). A less common cause is failure of the kidneys to respond to vasopressin (congenital nephrogenic diabetes insipidus).

Normally, vasopressin is synthesized in the hypothalamus and then stored by the posterior pituitary gland (neurohypophysis). When released into the general circulation, vasopressin acts on the distal and collecting tubules of the kidneys, increasing their water permeability and causing water reabsorption. The absence of vasopressin in diabetes insipidus allows the filtered water to be excreted in the urine instead of being reabsorbed and results in the passage of large quantities of dilute fluid throughout the body.

There are two types of pituitary diabetes insipidus. *Primary pituitary diabetes insipidus* (50% of patients) is familial or idiopathic in origin. The primary form may occur in neonates as a result of congenital malformation of the central nervous system (CNS), infection, trauma, or tumor. *Secondary pituitary diabetes insipidus* results from intracranial neoplastic or metastatic lesions, hypophysectomy or other types of neurosurgery, a skull fracture, or head trauma, which damages the neurohypophyseal structures. The secondary form of this disease can also result from infection, granulomatous disease, or vascular lesions.

A transient form of diabetes insipidus also occurs during pregnancy, usually after the fifth or sixth month of gestation. The condition usually spontaneously reverses after delivery.

Complications

Untreated diabetes insipidus can produce hypovolemia, hyperosmolality, circulatory collapse, loss of consciousness, and CNS damage. These complications are most likely if the patient has an impaired or absent thirst mechanism.

A prolonged urinary flow increase may produce chronic complications, such as bladder distention, enlarged caliceal, hydroureter, and hydronephrosis. Complications may result from underlying conditions, such as metastatic brain lesions, head trauma, and infections.

Assessment findings

The patient's history shows an abrupt onset of extreme polyuria (usually 4 to 16 L/day of dilute urine, but sometimes as much as 30 L/day), extreme thirst, and consumption of extraordinarily large volumes of fluid. The patient may report weight loss, dizziness, weakness, constipation, slight to moderate nocturia and, in severe cases, fatigue from inadequate rest caused by frequent voiding and excessive thirst. In children, reports of enuresis, sleep disturbances, irritability, anorexia, and decreased weight gain and linear growth are common.

On inspection, you may notice signs of dehydration, such as dry skin and mucous membranes, fever, and dyspnea. Urine is pale and voluminous. Palpation may reveal poor skin turgor, tachycardia, and decreased muscle strength. Hypotension may be present on blood pressure auscultation.

Diagnostic tests

To distinguish diabetes insipidus from other types of polyuria, urinalysis and a dehydration test may be ordered. Urinalysis reveals almost colorless urine of low osmolality (50 to 200 mOsm/kg of water, less than that of plasma) and of low specific gravity (less than 1.005).

The dehydration test (water deprivation test) is a simple, reliable way to diagnose diabetes insipidus and differentiate vasopressin deficiency from other forms of polyuria. It compares urine osmolality after dehydration with urine osmolality after vasopressin administration. Fluids are withheld long enough to result in stable hourly urine osmolality values (an hourly increase of 30 mOsm/kg of water for at least 3 successive hours). After the 3rd hour, the patient is given 5 units of aqueous vasopressin. Plasma osmolality is determined immediately before vasopressin administration, and urine osmolality is measured 30 and 60 minutes later. In diabetes insipidus, the increase in urine osmolality after vasopressin administration exceeds 9%. Patients with pituitary diabetes insipidus respond to exogenous vasopressin with decreased urine output and increased urine specific gravity. Patients who have nephrogenic diabetes insipidus show no response to vasopressin.

If a patient is critically ill, diagnosis shouldn't be delayed for more time-consuming tests; a diagnosis may be based on the following laboratory values:

- u urine osmolality—200 mOsm/kg
- u urine specific gravity—1.005
- u serum osmolality—300 mOsm/kg
- u serum sodium—147 mEq/L.

Treatment

Until the cause of the patient's diabetes insipidus is identified and eliminated, administration of various forms of vasopressin or a vasopressin stimulant can control fluid balance and prevent dehydration.

- u Aqueous vasopressin is a replacement agent administered by subcutaneous injection in doses of 5 to 10 units. Its duration of action ranges from 3 to 6 hours. This drug is used in the initial management of diabetes insipidus after head trauma or a neurosurgical procedure.
- u Desmopressin acetate, a synthetic vasopressin analogue, affects prolonged antidiuretic activity and has no pressor effects. It may be given orally, by nasal spray that is absorbed through mucous membranes, or by S.C. or I.V. injection. The duration of action of desmopressin acetate is 8 to 20 hours, depending on dosage.
- u Chlorpropamide (Diabinese), a sulfonylurea agent used in diabetes mellitus, is also sometimes used to stimulate endogenous release of antidiuretic hormone and is effective if some pituitary function is present.
- u Nephrogenic diabetes insipidus is treated with a low-sodium, high-protein diet and thiazide diuretics. The mild diuretic action reduces blood volume and enhances sodium and water reabsorption in the proximal tubule.

Nursing diagnoses

- u Altered growth and development u Altered oral mucous membrane u Altered urinary elimination u Anxiety u Energy field disturbance u Fear u Fluid volume deficit u Ineffective family coping: Disabling u Ineffective individual coping u Knowledge deficit

Key outcomes

- u The patient's laboratory values will return to normal.
- u The patient's fluid volume will remain within normal range.
- u The patient's intake will equal his output.
- u The patient will demonstrate age-appropriate skills and behavior to the extent possible.
- u The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behaviors.
- u The patient will avoid complications.

Nursing interventions

- u Make sure that you keep accurate records of the patient's hourly fluid intake and urine output, vital signs, and daily weight.
- u Closely monitor the patient's urine specific gravity. Also monitor serum electrolyte and blood urea nitrogen levels.
- u During dehydration testing, watch the patient for signs of hypovolemic shock. Monitor blood pressure, pulse rate, and body weight. Also watch for changes in mental or neurologic status.
- u If the patient has any complaints of dizziness or muscle weakness, institute safety precautions to help prevent injury.
- u Make sure that the patient has easy access to the bathroom or bedpan.
- u Provide meticulous skin and mouth care. Use a soft toothbrush and mild mouthwash to avoid trauma to the oral mucosa. If the patient has cracked or sore lips, apply petroleum jelly as needed. Use alcohol-free skin care products, and apply emollient lotion to the patient's skin after baths.
- u Use caution when administering vasopressin to a patient with coronary artery disease because the drug can cause coronary artery constriction. Closely monitor the patient's electrocardiogram, looking for changes and exacerbation of angina.
- u Urge the patient to verbalize feelings. Offer encouragement, and provide a realistic assessment of the situation.
- u Help the patient identify his strengths, and help him see how he can use these strengths to develop effective coping strategies.
- u As necessary, refer the patient to a mental health professional for additional counseling.
- u Advise the patient to wear a medical identification bracelet at all times. Tell him he should also always keep his medication with him.

Patient teaching

- u Before the dehydration test: Tell the patient to take nothing by mouth until the test is over, and explain the need for hourly urine tests, vital sign and weight checks and, if necessary, blood tests. Explain the risks involved in the test, but reassure the patient that he'll be closely monitored.
- u Instruct the patient and family members to identify and report signs of severe dehydration and impending hypovolemia.
- u Tell the patient to record his weight daily, and teach him and family members how to monitor intake and output and how to use a hydrometer to measure urine specific gravity.
- u Encourage the patient to maintain fluid intake during the day to prevent severe dehydration, but to limit fluids in the evening to prevent nocturia.
- u Inform the patient and family members about long-term hormone replacement therapy. Instruct them to take the medication as prescribed and to avoid abrupt discontinuation of the drug without the doctor's order. Teach them how to give S.C. or I.M. injections and how to use nasal applicators. Discuss the drug's adverse effects and when to report them.
- u Teach the parents of a child with diabetes insipidus about normal growth and development; discuss how their child may differ. Encourage the parents to identify the child's strengths and use them to develop coping strategies. Refer family members for counseling if necessary.

HYPERPITUITARISM

Hyperpituitarism, also called acromegaly and gigantism, is a chronic, progressive disease marked by hormonal dysfunction and startling skeletal overgrowth. The prognosis depends on the causative factor, but this disease usually reduces life expectancy.

Hyperpituitarism appears in two forms: acromegaly (rare) and gigantism. Acromegaly occurs after epiphyseal closure, causing bone thickening and transverse growth and visceromegaly. This form of hyperpituitarism occurs equally among men and women, usually between the ages of 30 and 50.

Gigantism begins before epiphyseal closure and causes proportional overgrowth of all body tissues. As the disease progresses, loss of other trophic hormones, such as thyroid-stimulating hormone, luteinizing hormone, follicle-stimulating hormone, and corticotropin, may cause dysfunction of the target organs.

Gigantism affects infants and children, causing them to grow to as much as three times the normal height for their age. As adults, they may eventually reach a height of more than 8' (2.4 m).

Causes

In most patients, the source of excessive growth hormone (GH) or human growth hormone secretion is a GH-producing adenoma of the anterior pituitary gland, usually macroadenoma (eosinophilic or mixed-cell). The etiology of the tumor is unclear. Occasionally, hyperpituitarism occurs in more than one family member, suggesting a genetic cause.

Complications

Prolonged effects of excessive GH secretion include arthritis, carpal tunnel syndrome, osteoporosis, kyphosis, hypertension, arteriosclerosis, heart enlargement, and heart failure. Acromegaly may result in blindness and severe neurologic disturbances due to compression of surrounding tissues by the tumor. Both gigantism and acromegaly can also cause signs of glucose intolerance and clinically apparent diabetes mellitus because of the insulin-antagonistic character of GH.

Assessment findings

The onset of acromegaly is gradual. The patient may report soft-tissue swelling and hypertrophy of the face and extremities at first. As the disease progresses, he may complain of diaphoresis, oily skin, fatigue, heat intolerance, weight gain, headaches, decreased vision, decreased libido, impotence, oligomenorrhea, infertility, joint pain (possibly from osteoarthritis), hypertrichosis, and sleep disturbances (related to obstructive sleep apnea).

Observation reveals an enlarged jaw, thickened tongue, enlarged and weakened hands, coarsened facial features, oily or leathery skin, and a prominent supraorbital ridge. You may also notice a deep, hollow-sounding voice, caused by laryngeal hypertrophy, and enlarged paranasal sinuses and tongue. Additional observations include irritability, hostility, and other psychological disturbances.

Inspection may reveal cartilaginous and connective tissue overgrowth, causing a characteristic hulking appearance and thickened ears and nose. Prognathism (projection of the jaw) becomes marked and may interfere with chewing. The fingers are thick, and the tips appear “tufted” or shaped like arrowheads on X-ray.

Gigantism develops abruptly, producing some of the same skeletal abnormalities seen in acromegaly. In infants, inspection reveals a highly arched palate, muscular hypotonia, slanting eyes, and exophthalmos. On palpation, patients commonly exhibit a characteristic moist, doughy, weak handshake.

Diagnostic tests

The tests that support a diagnosis of hyperpituitarism include GH radioimmunoassay, which shows increased plasma GH levels. Because GH isn’t secreted at a steady rate, a random sampling may be misleading. This test also shows increased levels of insulin-like growth factor I (somatocedin-C); these levels are a better screening alternative.

Glucose suppression test offers more reliable information. Glucose normally suppresses GH secretion; therefore, a glucose infusion that fails to suppress the hormone level to below the accepted norm of 2 ng/ml strongly suggests hyperpituitarism when combined with characteristic clinical features.

Skull X-ray, computed tomography scanning, or magnetic resonance imaging may help to locate the pituitary tumor, and bone X-rays show a thickening of the cranium (especially of frontal, occipital, and parietal bones) and of the long bones as well as osteoarthritis in the spine.

Treatment

The aim of treatment is to curb overproduction of GH by removing the underlying tumor. Removal occurs by cranial or transsphenoidal hypophysectomy or pituitary radiation therapy. In acromegaly, surgery is mandatory when a tumor is compressing surrounding healthy tissue. Postoperative therapy commonly requires replacement of thyroid, cortisone, and gonadal hormones. Adjunctive treatment may include bromocriptine, which inhibits GH synthesis, and octreotide acetate, a long-acting analogue of somatostatin that suppresses GH secretion in at least two-thirds of patients with acromegaly.

Nursing diagnoses

u Activity intolerance u Altered growth and development u Altered oral mucous membrane u Body image disturbance u Impaired physical mobility u Ineffective individual coping u Knowledge deficit u Pain u Self-esteem disturbance u Sensory or perceptual alterations (visual) u Sexual dysfunction

Key outcomes

- u The patient will demonstrate age-appropriate skills and behaviors to the extent possible.
- u The patient and family members will agree to seek help from peer support group or professional counselors.
- u The patient will express feelings of comfort.
- u The patient will express positive feelings about self.
- u The patient will be able to perform activities of daily living within the confines of the disease process.
- u The patient will be able to maintain joint mobility and range of motion (ROM).

Nursing interventions

- u The grotesque body changes and sexual dysfunction that occur in this disorder can cause severe psychological stress. Provide emotional support to help the patient cope with an altered body image. Encourage him to verbalize his feelings and discuss his fear of rejection by others. Provide a positive, but realistic, assessment of his situation. Encourage him to develop other interests that support a positive self-image and de-emphasize appearance. Refer him and family members for counseling to help them deal with body image changes and sexual dysfunction.
- u Be sensitive to any mood changes the patient experiences. Reassure him and family members that these changes result from hormonal imbalances caused by the disease and can be reduced with treatment.
- u If the patient has skeletal manifestations, such as arthritis of the hands or osteoarthritis of the spine, administer analgesics and provide comfort measures. To preserve joint function, perform or assist with ROM exercises. Apply heat or cold as ordered. Use pillows and splints to support painful extremities.
- u Evaluate muscle weakness, especially in the patient with late-stage acromegaly, by checking the strength of his handclasp. If it's very weak, help with tasks such as cutting food. Also help him to walk, and take other safety precautions.
- u Provide meticulous skin care. Keep the skin dry, and use oil-free skin cleansers and lotions.
- u Monitor serum glucose levels. Observe for signs of hyperglycemia, such as sweating, fatigue, polyuria, and polydipsia.
- u Remember that the tumor may cause vision problems. If the patient has hemianopia, stand where he can see you.

Care after transsphenoidal adenectomy or hypophysectomy

When the transsphenoidal approach is used, the sella turcica is entered from below, through the sphenoid sinus, and the tumor or other tissue is excised. An external incision is made between the upper gum and lip and an internal incision is made through the sella turcica and dura.

Postoperative nursing care includes assessing the patient for complications of fluid balance, preventing disruption of the incisions, preventing infection, and replacing cortisol.

Fluid balance

The patient is at greater risk for developing diabetes insipidus secondary to insufficient release of antidiuretic hormone (ADH). If this occurs, it's usually temporary because the hypothalamus continues to produce adequate amounts of ADH. It usually develops in the first 24 hours after surgery and is resolved within 14 days. Nursing care involves:

- monitoring intake and output closely, every 4 to 8 hours in the early postoperative period
- assessing for polyuria (greater than 200 ml/hr) and dilute urine
- weighing patient daily
- assessing for excessive thirst, a sign of diabetes insipidus
- administering desmopressin parenterally.

Preventing disruption of incisions

When the tumor is resected, the sella turcica is packed with muscle or fat from the abdomen or thigh. Bone or cartilage is used to construct a new floor for the sella turcica. The packing is strong, but it can be disrupted by increased intracranial pressure (ICP). Nursing interventions include:

- preventing any behaviors that could increase ICP (bending, sneezing, blowing nose, straining, or coughing)
- keeping the head of the bed elevated at least 30 degrees
- monitoring the patient for signs of respiratory distress
- teaching the patient to facilitate breathing by using diaphragmatic breathing
- teaching deep breathing, sighing, and mouth breathing to avoid coughing.
- giving frequent mouth care to prevent drying of mucous membranes.

Preventing infection

If the packing and incisions are disrupted, cerebrospinal fluid (CSF) leakage occurs. The patient's nose is packed for 24 to 48 hours after surgery. A gauze sling is worn under the nose to absorb drainage. The patient must be monitored for signs of a CSF leakage and measures must be taken to prevent infection. If a CSF leak occurs, meningitis can result. Consider the following while providing care:

- Look for signs of a CSF leak, including complaints of postnasal drip, frequent swallowing or complaints from the patient of the need to swallow, and appearance of a *halo ring* on the gauze sling. (CSF fluid is clear but forms a halo surrounding serous fluid when it's mixed with serous fluid.) CSF fluid may be tested for glucose content.
- Assess for rhinorrhea after nasal packing is removed. Tell the patient to report a runny nose.
- Use meticulous hand washing before and after contact with the patient.
- Provide frequent, gentle saline mouth rinses. Use soft sponges for cleaning teeth and avoid using a toothbrush.

Cortisol replacement

After a hypophysectomy, cortisol replacement is necessary to maintain life. I.V. cortisol is usually initiated preoperatively. The patient needs to be monitored for glucocorticoid deficiency. Other nursing interventions include:

- monitoring serum and fingerstick blood sugars
- monitoring serum sodium and potassium levels
- assessing for hypotension, excessive fatigue, persistent nausea, and vomiting
- administering corticosteroids and fluids as prescribed.

After hypophysectomy or transsphenoidal adenectomy:

- Monitor for signs of increased intracranial pressure (ICP) and intracranial bleeding (decreased level of consciousness, unequal pupils, decreased visual acuity, bradycardia, hypertension, and vomiting).
- Check blood glucose often. GH levels usually decrease rapidly after surgery, removing an insulin-antagonist effect in many patients and possibly precipitating hypoglycemia.
- Measure intake and output hourly, and report large increases in urine output. Transient diabetes insipidus, which sometimes occurs after surgery for hyperpituitarism, can cause such increases.
- If the transsphenoidal approach is used, the patient needs to have nasal packing in place for several days. Keep an airway at the bedside. The patient must breathe through his mouth, so give good mouth care. Pay special attention to the mucous membranes—which usually become very dry—and the incision site under the upper lip, at the top of the gum line.
- In the transsphenoidal approach, the surgical site is packed with a piece of tissue generally taken from a mid thigh donor site. Watch for cerebrospinal fluid leaks from the packed site and increased external nasal drainage or drainage into the nasopharynx. Additional surgery may be needed to repair the leak.
- Help the patient walk on the first or second day after surgery.
- Monitor for complications involving fluid balance, the incision, infection, or hormonal deficiency. (See [Care after transsphenoidal adenectomy or hypophysectomy.](#))

Patient teaching

- In your preoperative teaching, include an honest explanation of the procedure and its outcome, including what to expect during the recovery period. Stress the positive effects, which include limited postoperative problems and minimal pain.
- Instruct the patient to avoid vigorous coughing or sneezing in the immediate postoperative period to avoid increased ICP.
- Teach the surgery patient to do deep breathing through his mouth because he'll have nasal packing in place.
- Before discharge, emphasize the importance of continuing hormone replacement therapy, if ordered. Make sure the patient and family members understand how and when to take the hormones, and warn against stopping them suddenly.
- If the patient is taking bromocriptine, explain that nausea, light-headedness, and orthostatic hypotension are common at the beginning of therapy but usually subside. Other adverse effects include constipation and nasal congestion.
- Advise the patient to wear a medical identification bracelet at all times and to bring the hormone replacement schedule with him whenever he returns to the facility.
- Instruct the patient to have follow-up examinations at least once per year for the rest of his life because there is a slight chance that the tumor may recur.

HYPOPITUITARISM

Hypopituitarism is a complex syndrome marked by metabolic dysfunction, sexual immaturity, and growth retardation (when it occurs in childhood). It results from a deficiency of the hormones secreted by the anterior pituitary gland. The disorder is also known as panhypopituitarism.

Panhypopituitarism refers to a generalized condition caused by partial or complete failure of the gland to produce all six of the vital hormones: corticotropin,

thyroid-stimulating hormone (TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), growth hormone (GH), and prolactin. Partial hypopituitarism and complete hypopituitarism occur in adults and children; in children, these diseases can cause dwarfism and pubertal delay.

Total loss of all hormones is fatal without treatment, but the prognosis is good with adequate replacement therapy and correction of the underlying causes.

Causes

The most common cause of primary hypopituitarism is a tumor. Other causes include congenital defects (hypoplasia or aplasia of the pituitary gland); pituitary infarction (most often from postpartum hemorrhage); partial or total hypophysectomy by surgery, irradiation, or chemical agents; and, rarely, granulomatous disease, such as tuberculosis. Occasionally, primary hypopituitarism has no identifiable cause.

Secondary hypopituitarism stems from a deficiency of releasing hormones produced by the hypothalamus. The process may be idiopathic or result from infection, trauma, or tumor.

Complications

Any combination of deficits in the production of the six major hormones can occur. If the process is an evolving one (due to a hypothalamic destructive lesion), additional hormonal deficiencies may occur over time. Hypopituitarism can result in GH deficiency, TSH or corticotropin deficiency, and gonadotropin and prolactin deficiency. Pituitary apoplexy is a medical emergency. (See [What happens in pituitary apoplexy.](#))

ADVANCED PRACTICE

What happens in pituitary apoplexy

Five percent to 10% of patients with pituitary tumors develop pituitary apoplexy, a potentially life-threatening condition caused by hemorrhage into the tumor. Pituitary apoplexy usually occurs suddenly when rapid adenoma growth causes infarction or rupture of the tumor's thin-walled vessels. Patients with acromegaly, Cushing's disease, or large nonfunctioning tumors have a higher-than-average incidence of pituitary apoplexy.

Signs and symptoms

Assessment findings for pituitary apoplexy include:

- u sudden, severe headache
- u blurred vision
- u diplopia
- u blindness (from optic chiasma compression)
- u eye deviation and pupil dilation (from oculomotor nerve paralysis)
- u altered level of consciousness (possibly progressing to unconsciousness)
- u nausea and vomiting
- u hyperpyrexia
- u nuchal rigidity.

Diagnosis and treatment

Diagnosis is based on the patient's history and test results, which may include leukocytosis, xanthochromic or frankly bloody cerebrospinal fluid (CSF), elevated CSF pressure and protein concentration, or suprasellar extension (as shown by a computed tomography scan).

Treatment is controversial, but it may involve corticosteroid administration. If visual deterioration continues, surgical evacuation of the hematoma may be performed to preserve vision.

The patient's inability to cope with minor stressors can lead to a high fever, shock, coma, and death. In secondary hypopituitarism, damage to the posterior pituitary gland from infection, trauma, or tumor is occasionally extensive enough to cause diabetes insipidus.

Assessment findings

Physical findings depend on the specific pituitary hormones that are deficient, the patient's age, and the severity of the disorder. Typically, clinical features develop slowly and don't become apparent until 75% of the pituitary gland is destroyed. Assessment findings related to specific hormonal deficiencies include:

- u *GH deficiency.* Physical signs of GH deficiency may not be apparent in neonates. Growth retardation is usually apparent at age 6 months, although sometimes it may not be obvious until late childhood. In children, inspection reveals chubbiness from fat deposits in the lower trunk, short stature, delayed secondary tooth eruption, and delayed puberty. Growth continues at as little as half the normal rate—sometimes extending into the patient's twenties or thirties—to an average height of 4' (1.2 m), with normal proportions. Inspection of adults with GH deficiency discloses more subtle signs, such as fine wrinkles near the mouth and eyes.
- u *Gonadotropin (FSH and LH) deficiency.* In women, history discloses amenorrhea; dyspareunia, related to reduced vaginal secretions; infertility; and reduced libido. Inspection may discover breast atrophy, sparse or absent axillary and pubic hair, and dry skin. Men report weakness, impotence, and reduced libido. Inspection may show decreased muscle strength, testicular softening and shrinkage, and retarded secondary sexual hair growth.
- u *TSH deficiency.* Patients may report cold intolerance, constipation, increased or decreased menstrual flow, and lethargy. Children have severe growth retardation despite treatment. Inspection may disclose dry, pale, puffy skin and slow thought processes. Palpation may reveal bradycardia.
- u *Corticotropin deficiency.* Patient history discloses fatigue, nausea, vomiting, anorexia, and weight loss. Inspection may show depigmentation of the skin and nipples. Vital signs during periods of stress may reflect hypothermia and hypotension.
- u *Prolactin deficiency.* Patients commonly report absent postpartum lactation, amenorrhea, sparse or absent growth of pubic and axillary hair, and symptoms of thyroid and adrenocortical failure.
- u *Panhypopituitarism.* All six pituitary hormones are at least partially deficient. This may result in a host of mental and physical abnormalities, including lethargy, psychosis, orthostatic hypotension, bradycardia, and anemia.

Diagnostic tests

In suspected hypopituitarism, evaluation is used to confirm hormonal deficiency caused by impairment or destruction of the anterior pituitary gland. It's also used to rule out disease of the target organs (adrenals, gonads, and thyroid gland) or hypothalamus. Low serum levels of thyroxin, for example, indicate diminished thyroid gland function, but further tests are necessary to identify the source of this dysfunction as the thyroid, pituitary, or hypothalamus.

Radioimmunoassay showing decreased plasma levels of some or all pituitary hormones (except corticotropin, which may require more sophisticated testing), accompanied by target-organ hypofunction, suggests pituitary failure and eliminates target gland disease. Failure of thyrotropin-releasing hormone administration to increase TSH or prolactin concentrations rules out hypothalamic dysfunction as the cause of hormonal deficiency.

Gonadotropin-releasing hormone administered I.V. can be used to distinguish between pituitary and hypothalamic causes of gonadotropin deficiency.

Administering a dopamine antagonist, such as metoclopramide, allows evaluation of the prolactin secretory reserve. In patients with hypopituitarism, increased prolactin levels indicate a lesion in the hypothalamus or pituitary stalk.

Clomiphene, an estrogen antagonist, can also be used as a diagnostic agent.

Diagnosis of dwarfism requires measurement of GH levels in the blood after administration of regular insulin to induce hypoglycemia, or of levodopa, which causes hypotension. These drugs should provoke increased GH secretion. Persistently low GH levels, despite provocative testing, confirm GH deficiency.

Computed tomography scanning, magnetic resonance imaging, or cerebral angiography is used to confirm the presence of intrasellar or extrasellar tumors.

Two provocative tests are also used, but both require careful medical supervision because they may precipitate an adrenal crisis. Oral administration of metyrapone enables detection of the source of low hydroxycorticosteroid levels; the drug blocks cortisol synthesis, which should stimulate pituitary secretion of corticotropin. Insulin administration induces hypoglycemia and stimulates corticotropin secretion. Persistently low levels of corticotropin indicate pituitary or hypothalamic failure.

Treatment

Replacement of hormones normally secreted by the target glands is the most effective treatment for hypopituitarism and panhypopituitarism. Hormonal replacement includes cortisol, the most important drug; thyroxine; and androgens or cyclic estrogen. Prolactin doesn't need replacement. The patient of reproductive age may benefit from FSH and human chorionic gonadotropin to boost fertility. Free thyroxine levels should be monitored in patients with hypopituitarism, as TSH level becomes an unreliable marker for thyroid replacement.

Somatrem, identical to GH but the product of recombinant DNA technology, has replaced growth hormones derived from human sources. It's effective for treating dwarfism, stimulating growth increases of 4" to 6" (10.2 to 15.2 cm) in the first year of treatment. The growth rate tapers off in subsequent years. After pubertal changes occur, the effects of GH therapy are limited.

Occasionally, a child becomes unresponsive to GH therapy, even with larger doses, perhaps because of antibody formation against the hormone. In such patients, small doses of androgen may again stimulate growth, but extreme caution is necessary to prevent premature closure of the epiphyses. Children with hypopituitarism may also need adrenal and thyroid hormone replacement and, as they approach puberty, sex hormones.

Nursing diagnoses

⌞ Altered growth and development ⌞ Altered nutrition: Less than body requirements ⌞ Body image disturbance ⌞ Hypothermia ⌞ Ineffective individual coping ⌞ Knowledge deficit ⌞ Risk for infection ⌞ Self-esteem disturbance ⌞ Sensory or perceptual alterations (visual) ⌞ Sexual dysfunction

Key outcomes

- ⌞ The patient will maintain body weight.
- ⌞ The patient will maintain normal body temperature.
- ⌞ The patient will demonstrate age-appropriate skills and behavior to the extent possible.
- ⌞ The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behaviors.
- ⌞ The patient will voice feelings related to self-esteem.
- ⌞ The patient will express positive feelings about self.
- ⌞ The patient will avoid complications.

Nursing interventions

- ⌞ Until hormone replacement therapy is completed, monitor the results of all laboratory tests for hormonal deficiencies.
- ⌞ Monitor patients with panhypopituitarism for anorexia. Determine food preferences and encourage the patient to maintain an adequate calorie intake. Offer frequent small meals and keep accurate records of weight loss or gain.
- ⌞ Record vital signs every 4 to 8 hours, and monitor intake and output. Check eyelids, nail beds, and skin for pallor, which indicates anemia. Check neurologic status.
- ⌞ Observe for signs of pituitary apoplexy, a medical emergency.
- ⌞ Provide meticulous skin care, and use good hand-washing technique to prevent infection. Combat skin dryness with alcohol-free skin care products and an emollient lotion after bathing.
- ⌞ Keep the patient warm if his body temperature is low. Provide extra clothing and blankets and adjust room temperature, if possible.
- ⌞ During insulin testing, monitor closely for signs of hypoglycemia (initially, slow cerebation, tachycardia, and nervousness; later, seizures). Keep dextrose 50% in water available for I.V. administration to rapidly correct hypoglycemia.

ALERT To prevent orthostatic hypotension, keep the patient supine during levodopa testing .

- ⌞ Institute safety precautions for patients with impaired visual acuity to decrease the risk of injury.
- ⌞ Support parents in setting realistic goals for the child, based on his age and abilities.
- ⌞ Provide strong emotional support for the patient who's coping with changes in body appearance and sexual functioning. Encourage verbalization of feelings, and discuss fear of rejection by others.
- ⌞ Provide a positive, realistic assessment of the patient's situation. Encourage him to develop interests that support a positive self-image and de-emphasize appearance.
- ⌞ Refer parents and family members for psychological counseling or to appropriate community resources. Emotional stress increases as the child becomes older and more aware of his condition.

Patient teaching

- ⌞ Teach the patient and family members about the limitations imposed by the disease. If the patient has dwarfism, explain that these children often look younger than their chronological age and that they may grow in height more slowly than their peers do.
- ⌞ Review the treatment regimen with the patient and family members, especially long-term hormonal replacement therapy. Discuss the importance of taking the medication as ordered and of keeping regular follow-up appointments for blood studies.
- ⌞ If the patient needs GH replacement, teach him and his family members how to perform subcutaneous injections.
- ⌞ Teach the patient and family members measures to conserve the patient's energy, manage stressful situations, and prevent infections. Stress the importance of adequate rest to avoid fatigue, a balanced diet with adequate calories and fluids, good personal hygiene and hand-washing technique, and avoidance of people with colds or other infections.
- ⌞ Emphasize the importance of identifying and reporting emergency situations. If necessary, teach family members to administer steroids parenterally.

Thyroid disorders

Diseases of the thyroid include thyroid hormone deficiency and overproduction and gland inflammation and enlargement. With treatment, most of these disorders have a good prognosis; untreated, they progress to medical emergencies or irreversible disabilities.

HYPERTHYROIDISM

Thyroid hormone overproduction results in the metabolic imbalance hyperthyroidism, which is also called thyrotoxicosis. There are several types of hyperthyroidism.

(See [Other forms of hyperthyroidism](#).)

The most common form of hyperthyroidism is Graves' disease, which increases thyroxine (T₄) production, enlarges the thyroid gland (goiter), and causes multiple systemic changes. (See [Understanding simple goiter](#).) The incidence of Graves' disease is highest between ages 30 and 60, especially in people with family histories of thyroid abnormalities; only 5% of hyperthyroid patients are younger than age 15. With treatment, most patients can lead normal lives. However, thyrotoxic crisis or thyroid storm, an acute exacerbation of hyperthyroidism, is a medical emergency that can lead to life-threatening cardiac, hepatic, or renal failure. (See [What happens in thyrotoxic crisis](#).)

Causes

Hypothyroidism may result from genetic and immunologic factors. In Graves' disease, thyroid-stimulating antibodies bind to and then stimulate the thyroid-stimulating hormone (TSH) receptors of the thyroid gland. The trigger for this autoimmune disease is unclear. The increased incidence of the disease among monozygotic twins points to an inherited factor, probably with a polygenic inheritance pattern. Graves' disease occasionally coexists with other autoimmune endocrine abnormalities, such as diabetes mellitus, thyroiditis, and hyperparathyroidism. It's also associated with the production of autoantibodies (long-acting thyroid stimulator [LATS], LATS-protector, and human thyroid adenyl cyclase stimulator), possibly caused by a defect in suppressor-T-lymphocyte function that allows the formation of these autoantibodies.

ADVANCED PRACTICE

Other forms of hyperthyroidism

Besides Graves' disease, other forms of hyperthyroidism include toxic adenoma, toxic multinodular goiter, thyrotoxicosis factitia, functioning metastatic thyroid carcinoma, thyroid-stimulating hormone (TSH)-secreting pituitary tumor, subacute thyroiditis, and silent thyroiditis.

Toxic adenoma

A small, benign nodule in the thyroid gland, toxic adenoma secretes thyroid hormone and is the second most common cause of hyperthyroidism. The cause of toxic adenoma is unknown; its incidence is highest in elderly people.

Clinical effects are similar to those of Graves' disease except that toxic adenoma doesn't induce ophthalmopathy, pretibial myxedema, or acropachy. The presence of adenoma is confirmed by radioactive iodine (¹³¹I) uptake and thyroid scan, which show a single hyperfunctioning nodule suppressing the rest of the gland.

Treatment includes ¹³¹I therapy or surgery to remove the adenoma after antithyroid drugs achieve a euthyroid state.

Toxic multinodular goiter

Common in the elderly, this form of thyrotoxicosis involves overproduction of thyroid hormone by one or more autonomously functioning nodules with a diffusely enlarged gland.

Thyrotoxicosis factitia

This form of hyperthyroidism results from chronic ingestion of thyroid hormone for thyrotropin suppression in patients with thyroid carcinoma. It may also result from thyroid hormone abuse by persons trying to lose weight.

Functioning metastatic thyroid carcinoma

A rare disease, this carcinoma causes excess production of thyroid hormone.

TSH-secreting pituitary tumor

In this disorder, a TSH-secreting pituitary tumor causes overproduction of thyroid hormone.

Subacute thyroiditis

Subacute thyroiditis —a virus-induced granulomatous inflammation of the thyroid —produces transient hyperthyroidism associated with fever, pain, pharyngitis, and tenderness of the thyroid gland.

Silent thyroiditis

Silent thyroiditis is a self-limiting, transient form of thyrotoxicosis, with histologic thyroiditis but no inflammatory symptoms.

In a person with latent hyperthyroidism, excessive intake of iodine and, possibly, stress can precipitate clinical hyperthyroidism. Similarly, in a person with inadequately treated hyperthyroidism, stressful conditions, such as surgery, infection, toxemia of pregnancy, and diabetic ketoacidosis, can precipitate thyrotoxic crisis.

Complications

Thyroid hormones have widespread effects on almost all body tissues, so the complications of hypersecretion may be far-reaching and varied. Cardiovascular complications are most common in elderly persons and include arrhythmias, especially atrial fibrillation; cardiac insufficiency; cardiac decompensation; and resistance to the usual therapeutic dose of a digitalis glycoside. Additional complications include muscle weakness and atrophy, paralysis, osteoporosis, vitiligo and skin hyperpigmentation, corneal ulcers, myasthenia gravis, impaired fertility, decreased libido, and gynecomastia.

Assessment findings

The classic features of Graves' disease are an enlarged thyroid (goiter), nervousness, heat intolerance, weight loss despite increased appetite, sweating, frequent bowel movements, tremor, and palpitations. Exophthalmos is considered most characteristic but is absent in many patients with thyrotoxicosis.

Many other signs and symptoms are common because thyrotoxicosis profoundly affects virtually every body system.

u *central nervous system*—difficulty in concentrating because increased T₄ secretion accelerates cerebral function; excitability or nervousness due to increased basal metabolic rate; fine tremor, shaky handwriting, and clumsiness from increased activity in the spinal cord area that controls muscle tone; and emotional instability and mood swings, ranging from occasional outbursts to overt psychosis.

Understanding simple goiter

A simple (nontoxic) goiter is any enlargement of the thyroid gland not caused by inflammation or neoplasm. The thyroid mass increases to compensate for inadequate hormone synthesis. It's most common in females, occurring when thyroid hormone secretion fails to meet metabolic needs.

Sporadic goiter follows ingestion of goitrogenic drugs (such as propylthiouracil) and iodides or foods (such as rutabagas and cabbage). *Endemic goiter* results from geographically related nutritional factors, such as iodine-depleted soil. Inherited defects may contribute to either type of goiter.

The patient may report respiratory distress and dysphagia from compression of the trachea and esophagus and dizziness or syncope when raising her arms over her head. A firm, irregular enlargement and stridor caused by tracheal compression may be found.

Diagnostic tests reveal normal serum thyroid hormone levels; abnormalities rule out this diagnosis. Thyroid antibody titers are usually normal. ¹³¹I uptake is usually normal but may increase with iodine deficiency or a biosynthetic defect. Urinalysis may show low urinary excretion of iodine.

Treatment to reduce thyroid hyperplasia involves thyroid hormone replacement. Iodide administration often relieves goiters due to iodine deficiency. Sporadic goiter requires avoidance of goitrogenic drugs or food. Radioiodine ablation therapy aids some patients. Rarely, partial thyroidectomy is needed to relieve pressure on surrounding structures.

- u *skin, hair, and nails*—smooth, warm, flushed skin (patient sleeps with minimal covers and little clothing); fine, soft hair; premature graying and increased hair loss in both sexes; friable nails and onycholysis (distal nail separated from the bed); pretibial myxedema (dermopathy), producing thickened skin; and accentuated hair follicles, raised red patches of skin that are itchy and sometimes painful, with occasional nodule formation. Microscopic examination shows increased mucin deposits.
- u *cardiovascular system*—tachycardia; full, bounding pulse; wide pulse pressure; cardiomegaly; increased cardiac output and blood volume; visible point of maximal impulse; paroxysmal supraventricular tachycardia and atrial fibrillation (especially in elderly people); and, occasionally, a systolic murmur at the left sternal border.
- u *respiratory system*—dyspnea on exertion and at rest, possibly from cardiac decompensation and increased cellular oxygen utilization.
- u *GI system*—excessive oral intake with weight loss; nausea and vomiting due to increased GI motility and peristalsis; increased defecation; soft stools, or, with severe disease, diarrhea; and liver enlargement.
- u *musculoskeletal system*—weakness (especially in proximal muscles), fatigue, and muscle atrophy; rare coexistence with myasthenia gravis; possibly generalized or localized paralysis associated with hypokalemia; and occasional acropachy (soft-tissue swelling, accompanied by underlying bone changes where new bone formation occurs).
- u *reproductive system*—in females, oligomenorrhea or amenorrhea, decreased fertility, higher incidence of spontaneous abortions; in males, gynecomastia due to increased estrogen levels; in both sexes, diminished libido.
- u *eyes*—Exophthalmos (produced by the combined effects of accumulation of mucopolysaccharides and fluids in the retro-orbital tissues that force the eyeball outward, and of lid retraction that produces the characteristic staring gaze); occasional inflammation of conjunctivae, corneas, or eye muscles; diplopia; and increased tearing.

When thyrotoxicosis escalates to thyroid storm, these symptoms can be accompanied by extreme irritability, hypertension, tachycardia, vomiting, temperature up to 106° F (41° C), delirium, and coma.

ASSESSMENT TIP In elderly patients, consider apathetic thyrotoxicosis in patients who exhibit atrial fibrillation or depression.

Diagnostic tests

The following laboratory tests confirm the diagnosis of hyperthyroidism: Radioimmunoassay shows increased serum triiodothyronine (T₃) and T₄ concentrations, thyroid scan reveals increased uptake of radioactive iodine (¹³¹I) (This test is contraindicated in pregnant patients.), and thyrotropin-releasing hormone (TRH) stimulation test helps to confirm a diagnosis of hyperthyroidism if the TSH level fails to increase within 30 minutes after administration of TRH.

Other supportive test results show increased serum protein-bound iodine and decreased serum cholesterol and total lipid levels. Ultrasonography confirms subclinical ophthalmopathy.

Treatment

In hyperthyroidism, treatment consists of drugs, radioiodine, and surgery. Antithyroid drug therapy is used for children, young adults, pregnant women, and patients who refuse surgery or radioiodine treatment. Thyroid hormone antagonists include propylthiouracil (PTU) and methimazole, which block thyroid hormone synthesis.

Although hypermetabolic symptoms subside within 4 to 8 weeks after therapy begins, the patient must continue taking the medication for 6 months to 2 years. In many patients, concomitant propranolol is used to manage tachycardia and other peripheral effects of excessive sympathetic activity.

During pregnancy, antithyroid medication should be kept at the minimum dosage required to maintain normal maternal thyroid function and to minimize the risk of fetal hypothyroidism, even though most infants of hyperthyroid mothers are born with mild and transient hyperthyroidism. (Neonatal hyperthyroidism may even require treatment with antithyroid drugs and propranolol for 2 to 3 months.) Because exacerbation of hyperthyroidism sometimes occurs in the puerperium, continuous control of maternal thyroid function is essential. About 3 to 6 months postpartum, antithyroid drugs can be gradually decreased and thyroid function reassessed (drugs may be discontinued at that time). Mothers shouldn't breast-feed during treatment with antithyroid drugs because this can cause neonatal hypothyroidism.

Treatment with ¹³¹I consists of a single oral dose and is the treatment of choice for women past reproductive age or men and women not planning to have children. (Patients of reproductive age must give informed consent for this treatment because small amounts of ¹³¹I concentrate in the gonads.) During treatment, the thyroid gland picks up the radioactive element as it would regular iodine. Subsequently, the radioactivity destroys some of the cells that normally concentrate iodine and produce T₄, thus decreasing thyroid hormone production and normalizing thyroid size and function. In most patients, hypermetabolic symptoms diminish within 6 to 8 weeks after such treatment. However, some patients require a second dose.

Subtotal (partial) thyroidectomy is indicated for the patient under age 40 who has a very large goiter and whose hyperthyroidism has repeatedly relapsed after drug therapy. This surgery involves removing part of the thyroid gland, decreasing its size and capacity for hormone production. Preoperatively, the patient may receive iodides (Lugol's or potassium iodide solution), antithyroid drugs, or high doses of propranolol to help prevent thyroid storm. If euthyroidism isn't achieved, surgery should be delayed and propranolol should be administered to decrease the risk of cardiac arrhythmias that are caused by hyperthyroidism.

Therapy for hyperthyroid ophthalmopathy includes local applications of topical medications but may require high doses of corticosteroids. A patient with severe exophthalmos that causes pressure on the optic nerve may require surgical decompression to lessen pressure on the orbital contents.

PATHOPHYSIOLOGY

What happens in thyrotoxic crisis

Thyrotoxic crisis —also known as thyroid storm —is an acute manifestation of hyperthyroidism. It usually occurs in patients with preexisting (though often unrecognized) thyrotoxicosis. Left untreated, it's invariably fatal.

Pathophysiology

The thyroid gland secretes the thyroid hormones triiodothyronine (T₃) and thyroxine (T₄). When it overproduces them in response to any of the precipitating factors listed below, systemic adrenergic activity increases. This results in epinephrine overproduction and severe hypermetabolism, leading rapidly to cardiac, GI, and sympathetic nervous system decompensation.

Assessment findings

Initially, the patient may have marked tachycardia, vomiting, and stupor. If left untreated, he may experience vascular collapse, hypotension, coma, and death. Other findings may include a combination of irritability and restlessness; visual disturbance, such as diplopia; tremor and weakness; angina; or shortness of breath, a cough, and swollen extremities. Palpation may disclose warm, moist flushed skin and a high fever (beginning insidiously and rising rapidly to a lethal level).

Precipitating factors

Onset is almost always abrupt, evoked by a stressful event, such as trauma, surgery, or infection. Other less common precipitators include:

- u insulin-induced hypoglycemia or diabetic ketoacidosis
- u cardiovascular accident
- u myocardial infarction
- u pulmonary embolism
- u sudden discontinuation of antithyroid drug therapy
- u initiation of radioiodine therapy
- u preeclampsia
- u subtotal thyroidectomy with accompanying excess intake of synthetic thyroid hormone.

Treatment of thyrotoxic crisis includes administration of an antithyroid drug such as PTU, I.V. propranolol to block sympathetic effects, a corticosteroid to inhibit the conversion of T₃ to T₄ and to replace depleted cortisol, and an iodide to block release of the thyroid hormones. Supportive measures include nutrients, vitamins, fluid administration, and sedatives as necessary.

Nursing diagnoses

- u Altered nutrition: Less than body requirements u Altered thought processes u Body image disturbance u Decreased cardiac output u Diarrhea u Ineffective individual coping u Knowledge deficit u Risk for altered body temperature u Risk for fluid volume deficit

Key outcomes

- u The patient's vital signs will remain stable.
- u The patient's cardiac output will remain normal.
- u The patient's fluid volume will remain within normal parameters.
- u The patient's bowel movements will return to normal.
- u The patient's temperature will remain normothermic.
- u The patient will express positive feelings about self.

Nursing interventions

- u Keep accurate records of vital signs, weight, fluid intake, and urine output. Measure neck circumference daily to check for progression of thyroid enlargement.
- u Monitor serum electrolyte levels and check for hyperglycemia and glycosuria.
- u Monitor the patient's electrocardiogram for arrhythmias and ST-segment changes.
- u Monitor for signs of heart failure, such as dyspnea, jugular vein distention, pulmonary crackles, and peripheral or sacral edema.
- u Minimize physical and emotional stress. Try to balance rest and activity periods. Keep the patient's room cool and quiet and the lights dim. Encourage the patient to dress in loose-fitting, cotton clothing.
- u Consult a dietitian to ensure a nutritious diet with adequate calories and fluids. Offer frequent, small meals.
- u Monitor the frequency and characteristics of stools, and give antidiarrheal preparations as ordered. Provide meticulous skin care to minimize skin breakdown.
- u Reassure the patient and family members that mood swings and nervousness usually subside with treatment. Encourage the patient to verbalize feelings about changes in body image. Help him identify and develop coping strategies. Offer emotional support. Refer the patient and family members to a mental health counselor, if necessary.
- u If iodide is part of the treatment, mix it with milk, juice, or water to prevent GI distress and give it through a straw to prevent tooth discoloration.
- u Monitor the patient taking propranolol for signs of hypotension (dizziness and decreased urine output).
- u If the patient is taking PTU or methimazole, monitor complete blood count results periodically to detect leukopenia, thrombocytopenia, and agranulocytosis.
- u If the patient has exophthalmos or other ophthalmopathy, moisten the conjunctivae often with isotonic eyedrops.
- u Avoid excessive palpation of the thyroid, which can precipitate thyroid storm.

ALERT After thyroidectomy, check often for respiratory distress and keep a tracheotomy tray at the bedside.

After thyroidectomy:

- u Check the dressings for spots of blood, which may indicate hemorrhage into the neck. Change dressings and perform wound care, as ordered. Also check the back of the dressing for drainage. Keep the patient in semi-Fowler's position and support his head and neck with sandbags to ease tension on the incision.
- u Check for dysphagia or hoarseness from possible laryngeal nerve injury.
- u Watch for signs of hypocalcemia (tetany and numbness), a complication that results from accidental removal of the parathyroid glands during surgery.

Patient teaching

- u Stress the importance of regular medical follow-up visits after discharge because hypothyroidism may develop 2 to 4 weeks postoperatively and after ¹³¹I therapy. Advise the patient that he'll need lifelong thyroid hormone replacement. Encourage him to wear a medical identification bracelet and to carry his medication with him at all times.
- u Tell the patient who's had ¹³¹I therapy not to expectorate or cough freely because his saliva is radioactive for 24 hours. Stress the need for repeated measurement of serum thyroxine levels. Be sure he understands that he must not resume antithyroid drug therapy.
- u Instruct the patient taking PTU or methimazole to take these drugs with meals to minimize GI distress and to avoid over-the-counter cough preparations because many contain iodine.
- u Tell the patient taking propranolol to rise slowly after sitting or lying down to prevent feeling faint.
- u Instruct the patient taking antithyroid drugs or radioisotope therapy to identify and report symptoms of hypothyroidism.
- u Advise the patient with exophthalmos or other ophthalmopathy to wear sunglasses or eye patches to protect the eyes from light. If he has severe lid retraction, warn

him to avoid sudden physical movements that might cause the lid to slip behind the eyeball. Instruct him to report signs of decreased visual acuity.

HYPOTHYROIDISM IN ADULTS

In hypothyroidism in adults, metabolic processes slow down because of a deficiency of the thyroid hormones triiodothyronine (T₃) or thyroxine (T₄).

Hypothyroidism is classified as primary or secondary. Primary hypothyroidism stems from a disorder of the thyroid gland itself. Secondary hypothyroidism is caused by a failure to stimulate normal thyroid function or by a failure of target tissues to respond to normal blood levels of thyroid hormones. Either type may progress to myxedema, which is clinically much more severe and considered a medical emergency. (See [Managing myxedema coma.](#))

The disorder is most prevalent in women; in the United States, incidence is increasing significantly in people ages 40 to 50.

Causes

Hypothyroidism results from a variety of abnormalities that lead to insufficient synthesis of thyroid hormones. Common causes of hypothyroidism include thyroid gland surgery (thyroidectomy), irradiation therapy inflammation, chronic autoimmune thyroiditis (Hashimoto's disease), or inflammatory conditions, such as amyloidosis and sarcoidosis.

The disorder may also result from pituitary failure to produce thyroid-stimulating hormone (TSH), hypothalamic failure to produce thyrotropin-releasing hormone, inborn errors of thyroid hormone synthesis, inability to synthesize thyroid hormones because of iodine deficiency (usually dietary), or the use of antithyroid medications such as propylthiouracil.

Complications

Thyroid hormones affect almost every organ system in the body, so complications of hypothyroidism vary according to organs involved and the duration and severity of the condition.

Cardiovascular complications may include hypercholesterolemia with associated arteriosclerosis and ischemic heart disease. Poor peripheral circulation, heart enlargement, heart failure, and pleural and pericardial effusions may also occur.

WARNING

Managing myxedema coma

Myxedema coma is a medical emergency that often has a fatal outcome. Progression is usually gradual, but when stress aggravates severe or prolonged hypothyroidism, coma may develop abruptly. Examples of severe stress are infection, exposure to cold, and trauma. Other precipitating factors include thyroid medication withdrawal and the use of sedatives, narcotics, or anesthetics.

Patients in myxedema coma have significantly depressed respirations, so their partial pressure of carbon dioxide in arterial blood may increase. Decreased cardiac output and worsening cerebral hypoxia may also occur. The patient is stuporous and hypothermic, and her vital signs reflect bradycardia and hypotension.

Lifesaving interventions

If your patient becomes comatose, begin these interventions as soon as possible:

- u Maintain airway patency with ventilatory support if necessary.
- u Maintain circulation through I.V. fluid replacement.
- u Provide continuous electrocardiogram monitoring.
- u Monitor arterial blood gas measurements to detect hypoxia and metabolic acidosis.
- u Warm the patient by wrapping her in blankets. Don't use a warming blanket because it might increase peripheral vasodilation, causing shock.
- u Monitor body temperature until stable with a low-reading thermometer.
- u Replace thyroid hormone by administering large I.V. levothyroxine doses as ordered. Monitor vital signs because rapid correction of hypothyroidism can cause adverse cardiac effects.
- u Monitor intake and output and daily weight. With treatment, urine output should increase and body weight should decrease; if not, report this to the doctor.
- u Replace fluids and other substances, such as glucose. Monitor serum electrolyte levels.
- u Administer corticosteroids as ordered.
- u Check for possible sources of infection, such as blood, sputum, or urine, which may have precipitated coma. Treat infections or any other underlying illness.

GI complications include achlorhydria, pernicious anemia, and adynamic colon, resulting in megacolon and intestinal obstruction.

Anemia due to the generalized suppression of erythropoietin may result in bleeding tendencies and iron deficiency anemia. Other complications include conductive or sensorineural deafness, psychiatric disturbances, carpal tunnel syndrome, benign intracranial hypertension, and impaired fertility.

Assessment findings

The patient history may reveal vague and varied symptoms that developed slowly over time. The patient may report energy loss, fatigue, forgetfulness, sensitivity to cold, unexplained weight gain, and constipation. As the disorder progresses, signs and symptoms may include anorexia, decreased libido, menorrhagia, paresthesia, joint stiffness, and muscle cramping.

Inspection reveals characteristic alterations in the patient's overall appearance and behavior. These changes include decreased mental stability (slight mental slowing to severe obtundation) and a thick, dry tongue, causing hoarseness and slow, slurred speech.

You'll probably note dry, flaky, inelastic skin; puffy face, hands, and feet; periorbital edema; and drooping upper eyelids. Hair may be dry and sparse with patchy hair loss and loss of the outer third of the eyebrow. Nails may be thick and brittle with visible transverse and longitudinal grooves. You may also find ataxia, intention tremor, and nystagmus.

Palpation may reveal cool, doughy skin; weak pulse and bradycardia; weak muscles; sacral or peripheral edema, and delayed reflex relaxation time (especially in the Achilles tendon). The thyroid tissue itself may not be easily palpable unless a goiter is present.

Auscultation may show absent or decreased bowel sounds, hypotension, a gallop or distant heart sounds, and adventitious breath sounds. Percussion and palpation may reveal abdominal distention or ascites.

Diagnostic tests

Hypothyroidism is confirmed when radioimmunoassay with radioactive iodine (¹³¹I) shows low serum levels of T₃ and T₄. Supportive laboratory findings include the

following:

- Serum TSH levels are used to determine the primary or secondary nature of the disorder. An increased serum TSH level with hypothyroidism is due to thyroid insufficiency; a decreased TSH level is due to hypothalamic or pituitary insufficiency.
- Serum cholesterol, alkaline phosphatase, and triglycerides levels are elevated.
- Normocytic neurochronic anemia is present.
- In myxedema coma, laboratory tests also show low serum sodium levels, decreased pH, and increased PCO₂, indicating respiratory acidosis.
- Radioisotope scanning of the thyroid tissue identifies ectopic thyroid tissue.
- Skull X-ray, computed tomography scanning, and magnetic resonance imaging help to locate pituitary or hypothalamic lesions that may be the underlying cause of hypothyroidism.

ASSESSMENT TIP Screening of newborns and the elderly is a prevention measure to detect hypothyroidism. The elderly, especially women, often attribute signs and symptoms of hypothyroidism to effects of aging, and the diagnosis is overlooked.

Treatment

In hypothyroidism, recommended treatment consists of gradual thyroid hormone replacement with the synthetic hormone levothyroxine (T₄) and, occasionally, liothyronine (T₃). Treatment begins slowly, particularly in elderly patients, to avoid adverse cardiovascular effects; the dosage increases every 2 to 3 weeks until the desired response is obtained.

Rapid treatment may be necessary for patients with myxedema coma and those about to undergo emergency surgery (because of sensitivity to central nervous system depression). In these patients, both I.V. administration of levothyroxine and hydrocortisone therapy is warranted.

CULTURAL TIP In the United States, soil in the Great Lakes area is iodine deficient and therefore food grown in it is also deficient. Use of iodized salt provides sufficient amounts. In underdeveloped areas, prophylactic iodine supplements have successfully decreased the incidence of iodine-deficient goiter.

Nursing diagnoses

- Altered tissue perfusion (cardiopulmonary)
- Altered nutrition: More than body requirements
- Body image disturbance
- Chronic low self-esteem
- Constipation
- Decreased cardiac output
- Fluid volume excess
- Ineffective individual coping
- Knowledge deficit
- Risk for impaired skin integrity
- Sensory or perceptual alterations (auditory)

Key outcomes

- The patient will maintain adequate cardiac output.
- The patient's vital signs will remain stable.
- The patient's laboratory values will return to normal.
- The patient's fluid volume will be within normal parameters.
- The patient will consume adequate daily calorie requirements.
- The patient will express positive feelings about self.

Nursing interventions

- Routinely monitor and keep accurate records of the patient's vital signs, fluid intake, urine output, and daily weight.
- Monitor the patient's cardiovascular status. Auscultate heart and breath sounds, and watch closely for chest pain or dyspnea. Provide rest periods, and gradually increase activity to avoid fatigue and to decrease myocardial oxygen demand. Observe for dependent and sacral edema, apply antiembolism stockings, and elevate extremities to assist venous return.
- Encourage the patient to cough and breathe deeply to prevent pulmonary complications. Maintain fluid restrictions and a low-salt diet.
- Auscultate for bowel sounds, check for abdominal distention, and monitor the frequency of bowel movements. Provide the patient with a high-bulk, low-calorie diet and encourage activity to combat constipation and promote weight loss. Administer cathartics and stool softeners, as needed.
- Monitor mental and neurologic status. Observe the patient for disorientation, decreased level of consciousness, and hearing loss. If needed, reorient her to person, place, and time and use alternative communication techniques if she has impaired hearing. Explain all procedures slowly and carefully and avoid sedation, if possible. Provide a consistent environment to decrease confusion and frustration. Offer support and encouragement to the patient and her family.
- Provide meticulous skin care. Turn and reposition the patient every 2 hours if she's on extended bed rest. Use alcohol-free skin care products and an emollient lotion after bathing.
- Provide extra clothing and blankets for a patient with decreased cold tolerance. Dress the patient in layers and adjust room temperature, if possible.
- During thyroid replacement therapy, watch for symptoms of hyperthyroidism, such as restlessness, sweating, and excessive weight loss.
- Encourage the patient to verbalize her feelings and fears about changes in body image and possible rejection by others. Help her identify her strengths and use them to develop coping strategies and encourage her to develop interests that foster a positive self-image and de-emphasize appearance. Reassure the patient that her appearance will improve with thyroid replacement.

Patient teaching

- Help the patient and family members understand the patient's physical and mental changes. Teach them that hypothyroidism commonly causes mood changes and altered thought processes. Stress that these problems usually subside with proper treatment. Urge family members to encourage and accept the patient and to help her adhere to her treatment regimen. If necessary, refer the patient and family members to a mental health professional for additional counseling.
- Instruct the patient and family members to identify and report the signs and symptoms of life-threatening myxedema. Stress the importance of obtaining prompt medical care for respiratory problems and chest pain.
- Teach the patient and family about long-term hormone replacement therapy. Emphasize that lifelong administration of this medication is necessary, that she should take it exactly as prescribed, and that she should never abruptly discontinue it. Advise the patient always to wear a medical identification bracelet and to carry her medication with her.
- Advise the patient and family members to keep accurate records of daily weight.
- Instruct the patient to eat a well-balanced diet that is high in fiber and fluids to prevent constipation, to restrict sodium to prevent fluid retention, and to limit calories to minimize weight gain.
- Tell the patient to schedule activities to avoid fatigue and to get adequate rest.

HYPOTHYROIDISM IN CHILDREN

A deficiency of thyroid hormone secretion during fetal development or early infancy results in congenital hypothyroidism, formerly called cretinism. Hypothyroidism is three times more common in girls than in boys.

Early diagnosis and treatment allow the best prognosis, and infants treated before age 3 months usually grow and develop normally. However, children with deficient thyroid activity who remain untreated beyond age 3 months and children with acquired hypothyroidism who remain untreated beyond age 2 suffer irreversible mental retardation.

Causes

In infants, hypothyroidism usually results from defective embryonic development that causes congenital absence or underdevelopment of the thyroid gland. The next most common cause is an inherited enzymatic defect in the synthesis of thyroxine (T₄), caused by an autosomal recessive gene. Less frequently, antithyroid drugs or a profound iodine deficiency during pregnancy produce hypothyroidism in infants. In children older than age 2, hypothyroidism usually results from chronic

autoimmune thyroiditis.

Complications

Hypothyroidism that results from intrauterine iodine deficiency is associated with irreversible neurologic and intellectual deficiencies. If it isn't identified and treated in the first few months of life, it can cause severe mental retardation and skeletal malformations, such as dwarfism, epiphyseal degeneration, and bone and muscle dystrophy.

Children with untreated hypothyroidism may also suffer the same complications as in adult-onset hypothyroidism: life-threatening myxedema, respiratory compromise, cardiovascular dysfunction, anemias, megacolon, and intestinal obstruction.

Assessment findings

Clinical manifestations of hypothyroidism may not be visible at birth but are usually evident within the first 6 months. The parent may report feeding difficulties, constipation, somnolence, inactivity, respiratory problems, and an infrequent, hoarse cry.

Inspection of the infant with hypothyroidism may show a protruding abdomen, umbilical hernia, and slow, awkward movements. The skin is usually pale, mottled, dry, and flaky. The hair is coarse, dull, and brittle. Prolonged physiologic jaundice may also be visible. The tongue is large and protruding and may obstruct respiration, resulting in dyspnea and mouth breathing. Characteristic abnormal facial features may include a short forehead; puffy, wide-set eyes (periorbital edema); wrinkled eyelids; a broad, short, upturned nose; and a dull expression.

In the child over age 2, inspection may reveal delayed tooth eruption and early decay. Growth retardation is obvious, evidenced by short stature (due to delayed epiphyseal maturation, particularly in the legs), obesity, and a head that appears abnormally large because the arms and legs are stunted. An older child may show delayed or accelerated sexual development.

In both infants and children, palpation may disclose hypotonic abdominal muscles, cold skin, a weak pulse, bradycardia, and diminished deep tendon reflexes. The thyroid tissue itself may not be palpable unless a goiter is present. Auscultation may reveal hypotension, absent or diminished bowel sounds, abnormal heart sounds, and adventitious breath sounds.

Diagnostic tests

Serum thyroid-stimulating hormone (TSH) level is high and associated with low T₄ and triiodothyronine (T₃) levels in hypothyroidism. Because early detection and treatment can minimize the effects of hypothyroidism, many states require measurement of infant thyroid hormone levels at birth.

Thyroid scan (¹³¹I uptake test) shows decreased uptake levels and confirms the absence of thyroid tissue in children.

Gonadotropin levels are increased and compatible with sexual precocity in older children. These findings may coexist with hypothyroidism.

X-rays of the hip, knee, and thigh reveal the absence of the femoral or tibial epiphyseal line and delayed skeletal development that is markedly inappropriate for the child's chronological age.

Skull X-ray, computed tomography scan, and magnetic resonance imaging may show a pituitary or hypothalamic lesion.

T₄ level, if low and associated with a low TSH level, suggests hypothyroidism secondary to hypothalamic or pituitary disease, a rare condition.

Treatment

Treatment for infants under age 1 consists of replacement therapy with oral levothyroxine, beginning with moderate doses. Dosage gradually increases to levels sufficient for lifelong maintenance. (Rapid increase may precipitate thyrotoxicity.) Doses are proportionately higher in children than in adults because children metabolize thyroid hormone more quickly.

Levothyroxine is also used to treat older children.

Nursing diagnoses

u Altered growth and development u Altered nutrition: Less than body requirements u Body image disturbance u Constipation u Hypothermia u Ineffective airway clearance u Ineffective family coping: Compromised u Knowledge deficit u Self-esteem disturbance

Key outcomes

- u The patient will demonstrate age-appropriate skills and behaviors to the extent possible.
- u The patient will consume daily calorie requirements.
- u The patient will maintain a patent airway and adequate ventilation.
- u The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behavior.
- u The patient will express positive feelings about self.

Nursing interventions

- u Keep accurate records of the infant's vital signs, weight, fluid intake, urine output, and respiratory and neurologic status.
- u Monitor body temperature every 3 hours by the axillary or inguinal route. If indicated, place the infant in a warming unit. If she's in an open crib, avoid heat loss by keeping her warm with pajamas, blankets, and a stocking cap.
- u Observe the infant's sucking, swallowing, gag, and cough reflexes. Have suction equipment nearby. Try different nipple types, such as a "preemie" nipple, or use a nipple shield to help prevent feeding difficulties. Place the infant in a lateral or prone position to prevent airway obstruction.
- u Monitor the infant's bowel sounds and frequency of bowel movements.
- u Provide meticulous skin care, using alcohol-free skin care products and emollient lotion after bathing. Turn and reposition the infant every 2 hours.
- u Encourage parents to verbalize their feelings about the patient's condition. Encourage the older child to verbalize her feelings about altered body image and to discuss fear of rejection by others. Provide emotional support and a realistic assessment of the child's condition. Refer family members to community support groups and, if necessary, to a mental health professional for additional counseling.
- u Encourage the child and family members to identify their strengths and use them to develop coping strategies. Assist the child to develop interests that foster a positive self-image and de-emphasize appearance. Involve the parents and child in decision making.

Patient teaching

- u Inform parents that the child requires lifelong treatment with thyroid supplements. Teach them to identify and report signs of overdose: rapid pulse rate, irritability, insomnia, fever, sweating, and weight loss. Stress the need to comply with treatment to prevent further mental impairment. Reassure them that thyroid replacement, when started early, reverses many of the effects of hypothyroidism.
- u Advise the parents to have the child wear a medical identification bracelet.
- u Tell parents to feed the child a high-fiber, low-calorie diet and encourage physical activity to avoid excess weight gain and constipation.
- u Teach parents about normal growth and development and their child's limitations. Advise them that she may be slower at achieving developmental milestones.

u To prevent infantile hypothyroidism, emphasize the importance of adequate nutrition during any future pregnancy, including iodine-rich foods and iodized salt. If the patient must restrict sodium, she should take an iodine supplement.

THYROIDITIS

Several disorders that involve inflammation of the thyroid gland are categorized as thyroiditis.

Autoimmune thyroiditis (long-term inflammatory disease) or *Hashimoto's thyroiditis* (lymphadenoid goiter) is a common chronic inflammatory disease of the thyroid gland in which autoimmune factors play a prominent role. It occurs most often in middle-aged women and is the most common cause of sporadic goiter in children.

Postpartum thyroiditis (silent thyroiditis) is another form of autoimmune thyroiditis that occurs in women within 1 year of the delivery.

Subacute thyroiditis (granulomatous, giant cell, silent, or de Quervain's thyroiditis) is a transient inflammation of the thyroid gland.

Miscellaneous thyroiditis may be classified as acute suppuratory chronic infective and chronic infective. Thyroiditis is more common in women than in men.

Riedel's thyroiditis causes intense fibrosis of the thyroid and surrounding structures, leading to an induration of the tissues in the neck, and may be associated with mediastinal and retroperitoneal fibrosis. This rare disorder needs to be differentiated from thyroid neoplasm.

Causes

Each type of thyroiditis has a different etiology. Hashimoto's thyroiditis is thought to result from lymphocytic infiltration of the thyroid gland and formation of antibodies to thyroid antigens in the blood. Glandular atrophy and Graves' disease are linked to this type of thyroiditis.

Subacute thyroiditis is viral and may follow mumps, influenza, coxsackievirus, or adenovirus infections.

Miscellaneous thyroiditis results from bacterial invasion of the gland due to acute suppurative thyroiditis; to tuberculosis, syphilis, actinomycosis, or other infectious agents in chronic infection; and to sarcoidosis and amyloidosis in chronic reinfective thyroiditis.

Riedel's thyroiditis is a rare condition with unknown etiology.

Complications

Thyroiditis complications depend on the type of inflammation. In Hashimoto's thyroiditis, they include compression of the surrounding tissues by the goiter and malignant lymphomas of the thyroid gland (rare). Subacute thyroiditis may lead to a permanent hypothyroid or hyperthyroid condition. In pyogenic thyroiditis, rupture of an abscess into the mediastinum, trachea, or esophagus may occur. Riedel's thyroiditis may cause hypothyroidism, tracheal or esophageal compression, necrosis of the compressed tissues, and hemorrhage.

Assessment findings

The patient's history may reveal a recent viral or bacterial infection, or a disorder such as systemic lupus erythematosus, rheumatoid arthritis, pernicious anemia, or Graves' disease. The patient may report the gradual onset of hypothyroid-like symptoms, such as sensitivity to cold, fatigue, and weight gain. Occasionally, symptoms of hyperthyroidism occur, such as heat intolerance, nervousness, and weight loss despite increased appetite. The patient may also complain of local pain or pain referred to the lower jaw, ear, or occiput; dysphagia; dyspnea; asthenia; and malaise.

On inspection, you may notice enlargement of the thyroid gland. In Hashimoto's thyroiditis, goiter is the outstanding clinical feature. The skin over the thyroid gland may be reddened, and in Riedel's thyroiditis, the neck tissues may be indurated.

Findings on palpation vary, depending on the type of thyroiditis. In Hashimoto's disease, the thyroid gland feels small, firm, and finely nodular, with a characteristic bandlike depression circling the gland and creating a butterfly shape. A small lymph node (Delphian node) found in the midline above the isthmus is palpable only in Hashimoto's thyroiditis or thyroid cancer. In the subacute form, palpation reveals pain over the thyroid and nodularity that may be unilateral but usually involves other areas of the gland. In the pyogenic or infective form, swelling and warmth of the overlying skin suggest an infectious process. And in Riedel's thyroiditis, a woody, hard enlargement that feels “anchored” to surrounding structures is palpable. The fibrosis may compress the trachea or the esophagus.

Auscultation may reveal stridor due to compression of the thyroid gland on the trachea.

Diagnostic tests

Precise diagnosis depends on the type of thyroiditis.

In Hashimoto's thyroiditis, thyroid failure is evidenced by an increase in thyroid-stimulating hormone (TSH), decreasing titers of triiodothyronine and thyroxine, and high titers of antimicrosomal and antithyroglobulin antibodies. Histologic confirmation by fine-needle biopsy is usually performed. Autoimmune processes show high titers of thyroglobulin and microsomal antibodies in the serum.

In subacute thyroiditis, thyroid hormone levels may be elevated, suppressed, or normal, depending on the phase of the disorder. Protein-bound iodine levels are elevated. During the thyrotoxic phase, TSH levels are low and fail to respond to thyrotropin-releasing hormone. TSH levels then increase in the hypothyroid phase. Radioactive iodine (¹³¹I) uptake is suppressed, and erythrocyte sedimentation rate, white blood cell (WBC) count, and hepatic enzyme levels also increase. Thyroid antibodies may appear transiently low in the serum. A thyroid scan may show isolated areas of function or total failure to visualize the gland.

An elevated WBC count accompanying physical symptoms suggests chronic infective or noninfective thyroiditis. A biopsy of the thyroid tissue for Gram stain, culture, microscopy, and histologic examination may be performed. Radioisotope scanning and ultrasonography may be used to isolate the infected area. ¹³¹I uptake and serum hormone levels are usually within normal limits.

In Riedel's thyroiditis, ¹³¹I uptake is normal or decreased. Some patients may have elevated titers of antimicrosomal antibodies but not as high as in Hashimoto's thyroiditis.

Treatment

Appropriate treatment varies with the type of thyroiditis. Drug therapy includes levothyroxine for accompanying hypothyroidism, analgesics and anti-inflammatory drugs for mild subacute granulomatous thyroiditis, propranolol for transient hyperthyroidism, and steroids for severe episodes of acute illness. Suppurative thyroiditis requires antibiotic therapy. A partial thyroidectomy may be necessary to relieve tracheal or esophageal compression in Riedel's thyroiditis.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Body image disturbance u Impaired swallowing u Ineffective airway clearance u Ineffective individual coping u Knowledge deficit u Pain

Key outcomes

- u The patient's airway will remain patent.
- u The patient will express feelings of comfort.
- u The patient will consume adequate daily calorie requirements.
- u The patient will express positive feelings about self.
- u The patient will avoid complications.

Nursing interventions

- u Monitor the patient's respiratory status. Help him find a position that facilitates breathing and tell him to avoid lying supine. Elevate the head of the bed 90 degrees during mealtimes and for 30 minutes afterward to decrease the risk of aspiration. Keep suction equipment available.
- u Consult the dietitian to find nutritious foods that the patient can swallow easily. Be sure the patient consumes adequate calories.
- u Provide frequent mouth care and lubricate the patient's lips to prevent cracks and blisters. Provide meticulous skin care.
- u Keep accurate records of vital signs, weight, fluid intake, and urine output. Measure the patient's neck circumference daily and record progressive enlargement.
- u If the patient has a fever, provide comfort measures. Administer analgesics and antipyretics as ordered. Encourage the patient to drink plenty of fluids.
- u Encourage the patient to verbalize his feelings and fears about body image changes and being rejected by others. Offer emotional support, and help the patient identify his strengths for use in coping. Refer him to a mental health professional for additional counseling, if necessary.

ALERT After thyroidectomy, monitor the patient's vital signs every 15 to 30 minutes until stable. Watch for signs of tetany secondary to accidental parathyroid injury during surgery. Keep 10% calcium gluconate available for I.V. use, if needed. Check dressings frequently for excessive bleeding. Watch for signs of airway obstruction, such as difficulty talking or increased swallowing, and keep tracheotomy equipment handy.

Patient teaching

- u Teach the patient and family members to identify and report signs of respiratory distress, thyrotoxicity, hyperthyroidism, and hypothyroidism.
- u Advise the patient that lifelong hormone replacement therapy is necessary after a thyroidectomy. Encourage him to wear a medical identification bracelet and to carry his medication with him at all times.

Parathyroid disorders

The parathyroid glands regulate calcium balance, so undersecretion (hypoparathyroidism) or oversecretion (hyperparathyroidism) of parathyroid hormone can cause serious complications.

HYPERPARATHYROIDISM

Hyperparathyroidism is characterized by overactivity of one or more of the four parathyroid glands. It results in excessive secretion of parathyroid hormone (PTH). Increased PTH levels act directly on the bone and kidney tubules, causing an increase of calcium in the extracellular fluid that can't be compensated for by renal excretion or uptake into the soft tissues or skeleton.

Hyperparathyroidism is most common in women (especially those past menopause), with onset usually occurring between ages 35 and 65. The disorder is classified as primary or secondary, based on its etiology.

Causes

In primary hyperparathyroidism, one or more of the parathyroid glands enlarges, increasing PTH secretion and elevating serum calcium levels. The most common cause is a single adenoma. Other causes include a genetic disorder or multiple endocrine neoplasia.

In secondary hyperparathyroidism, excessive compensatory production of PTH stems from a hypocalcemia-producing abnormality outside the parathyroid gland, which causes a resistance to the metabolic action of PTH. Some hypocalcemia-producing abnormalities are vitamin D deficiency, chronic renal failure, or osteomalacia due to laxative abuse or phenytoin.

Complications

Untreated hyperparathyroidism damages the skeleton and kidneys from hypercalcemia. Bone and articular problems, such as chondrocalcinosis, osteoporosis, subperiosteal resorption, occasional severe osteopenia, erosions of the juxta-articular surface, subchondral fractures, traumatic synovitis, and pseudogout, may occur. Renal complications include nephrolithiasis; hypercalciuria; renal calculi, colic, and insufficiency; and renal failure.

Other possible complications include peptic ulcers, cholelithiasis, cardiac arrhythmias, vascular damage, and heart failure. Severe hypercalcemia can cause parathyroid poisoning, which includes central nervous system changes, renal failure, rapid precipitation of calcium throughout soft tissues, and possibly coma.

ADVANCED PRACTICE

Surgery for patients with primary hyperparathyroidism

Patients with primary hyperparathyroidism should be considered for surgery when:

- u calcium levels are more than or 1 mg/dl above normal
- u osteoporosis or hypercalcemia is present
- u recurrent peptic ulcer disease is present
- u nephrolithiasis is present
- u impaired kidney function is noted
- u the patient is young or consistent follow-up values are unavailable.

Assessment findings

The clinical effects of primary hyperparathyroidism result from hypercalcemia and are typically present in several body systems:

- u *renal*—nephrocalcinosis due to elevated levels of calcium and, possibly, recurring nephrolithiasis, which may lead to renal insufficiency. (Renal manifestations, including polyuria, are the most common effects of hyperparathyroidism.)
- u *skeletal and articular*—chronic low back pain and easy fracturing due to chondrocalcinosis; osteopenia and osteoporosis, especially on the vertebrae; erosions of the juxta-articular surface; subchondral fractures; traumatic synovitis; and pseudogout
- u *GI*—pancreatitis, causing constant, severe epigastric pain that radiates to the back; peptic ulcers, causing abdominal pain, anorexia, nausea, and vomiting
- u *neuromuscular*—muscle weakness and atrophy, particularly in the legs

- *central nervous system*—psychomotor and personality disturbances, depression, overt psychosis, stupor and, possibly, coma
- *other*—skin necrosis, cataracts, calcium microthrombi to lungs and pancreas, polyuria, anemia, and subcutaneous calcification.

Diagnostic tests

Serum PTH with accompanying hypercalcemia confirms the diagnosis in primary disease.

X-rays reveal diffuse bone demineralization, bone cysts, outer cortical bone absorption, and subperiosteal erosion of the phalanges and distal clavicles in primary disease.

X-ray spectrophotometry or other microscopic examinations of the bone demonstrate increased bone turnover in primary disease.

Esophagography, thyroid scan, parathyroid thermography, ultrasonography, thyroid angiography, computed tomography scan, and magnetic resonance imaging can help to locate parathyroid lesions.

Supportive laboratory tests reveal decreased serum phosphorus levels and elevated urine and serum calcium and serum chloride in primary disease.

Hyperparathyroidism may also increase urine acid and creatinine levels and increase basal acid secretion and serum immunoreactive gastrin. Increased serum amylase may indicate acute pancreatitis.

In secondary hyperparathyroidism, laboratory test findings show normal or slightly decreased serum calcium levels and variable serum phosphorus levels, especially when hyperparathyroidism is due to rickets, osteomalacia, or renal disease. Other laboratory values and physical examination findings are used to identify the cause of secondary hyperparathyroidism.

Treatment

Primary hyperparathyroidism may be treated by surgical removal of the adenoma or, depending on the extent of hyperplasia, removal of all but half of one gland (the remaining part is necessary to maintain normal PTH levels). Although surgery may relieve bone pain within 3 days, renal damage may be irreversible. (See [Surgery for patients with primary hyperparathyroidism.](#))

Preoperatively—or if surgery isn't feasible or necessary—other treatments can decrease calcium levels. Such treatments include forcing fluids; limiting dietary intake of calcium; promoting sodium and calcium excretion through forced diuresis using normal saline solution (up to 6 L in life-threatening circumstances), furosemide, or ethacrynic acid; and administering oral sodium or potassium phosphate, calcitonin, or plicamycin.

To prevent postoperative magnesium and phosphate deficiencies, the patient receives I.V. magnesium and phosphate or sodium phosphate solution given orally or by retention enema. In addition, during the first 4 or 5 days after surgery when serum calcium falls to low-normal levels, supplemental calcium may be necessary; vitamin D or calcitriol also may be used to increase serum calcium levels.

The goal of treatment for patients with secondary hyperparathyroidism is to correct the underlying cause of parathyroid hypertrophy. Treatment includes vitamin D therapy or, for the patient with renal disease, aluminum hydroxide for hyperphosphatemia. The patient with renal failure requires dialysis—possibly for the rest of her life—to lower calcium levels. In the patient with chronic secondary hyperparathyroidism, the enlarged glands may not revert to normal size and function even after calcium levels have been controlled.

Glucocorticoids are effective inhibitors of bone resorption and may be particularly useful in treating hypercalcemia associated with certain cancers.

Nursing diagnoses

- Activity intolerance
- Altered nutrition: Less than body requirements
- Altered thought processes
- Anxiety
- Body image disturbance
- Decreased cardiac output
- Fear
- Fluid volume excess
- Ineffective individual coping
- Knowledge deficit
- Pain

Key outcomes

- The patient will maintain current weight.
- The patient will express feelings of comfort and decreased pain.
- The patient will maintain adequate cardiac output.
- The patient's fluid volume will remain within normal parameters.
- The patient will perform activities of daily living without excessive fatigue.
- The patient will express positive feelings about self.
- The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping mechanisms.

Nursing interventions

- Before treatment, obtain baseline serum potassium, calcium, phosphate, and magnesium levels because they may change abruptly during treatment.
- Record intake and output during hydration to reduce serum calcium levels. Strain urine to check for renal calculi. Provide at least 3 L of fluid per day, including cranberry or prune juice to increase urine acidity and help prevent calculus formation.
- Auscultate the lungs regularly, listening for signs of pulmonary edema in the patient receiving large amounts of normal saline solution, especially if she has pulmonary or cardiac disease. Monitor the patient on digitalis for elevated serum calcium levels.
- Take safety precautions to minimize the risk of injury from a fall. Help the patient walk, keep the bed in the lowest position, and raise the side rails. Lift the immobilized patient carefully to minimize stress on the bones.
- Schedule care to allow the patient with muscle weakness as much rest as possible. Gradually increase activity according to her tolerance. Moderate weight-bearing activities are more beneficial than exercising in a bed or chair.
- Provide comfort measures to alleviate bone pain. Help the patient to turn and reposition her every 2 hours. Support the affected extremities with pillows. Use extreme care when lifting the patient. Provide analgesics as ordered.
- Monitor for signs of peptic ulcer and administer antacids, as appropriate. Consult a dietitian to plan a diet with adequate calories.
- Encourage the patient to verbalize her feelings about body image changes and rejection by others. Offer emotional support and help her to develop coping strategies. Refer her to a mental health professional for additional counseling, if necessary.

After parathyroidectomy:

- Monitor vital signs, respiratory status, and hourly urine output. Check for signs of increased neuromuscular irritability.
- Keep a tracheotomy tray and an endotracheal tube at the bedside. Maintain seizure precautions. Observe for postoperative complications, such as laryngeal nerve damage or hemorrhage.
- Check for swelling at the operative site. Place the patient in semi-Fowler's position, and support her head and neck with sandbags to decrease edema that may cause pressure on the trachea.

ALERT Be alert for complaints of tingling in the hands and around the mouth. If these symptoms don't subside quickly, they may be prodromal signs of tetany, so keep I.V. calcium gluconate or calcium chloride available for emergency administration.

- Help the patient walk as soon as possible after surgery, even though she may find this uncomfortable. Pressure on bones speeds up bone recalcification.
- Check laboratory results for low serum calcium and magnesium levels.

- u Monitor the patient's mental status and watch for listlessness. Check for muscle weakness and psychiatric symptoms in the patient with persistent hypercalcemia.

Patient teaching

- u Before discharge, advise the patient of possible adverse reactions to drug therapy.
- u Teach the patient and family members to identify and report signs of tetany, respiratory distress, and renal dysfunction.
- u Emphasize the need for periodic blood tests.
- u If the patient didn't have surgery to correct hyperparathyroidism, warn her to avoid calcium-containing antacids and thiazide diuretics.
- u Encourage the patient to wear a medical identification bracelet.

HYPOPARATHYROIDISM

A deficiency in parathyroid hormone (PTH) secretion by the parathyroid glands or the decreased action of PTH in the periphery causes hypoparathyroidism. Because the parathyroid glands primarily regulate calcium balance, hypoparathyroidism causes hypocalcemia, which produces neuromuscular symptoms ranging from paresthesia to tetany.

PTH normally maintains serum calcium levels by increasing bone resorption and by stimulating renal conversion of vitamin D to its active form, which enhances GI absorption of calcium. PTH also maintains the inverse relationship between serum calcium and phosphate levels by inhibiting phosphate reabsorption in the renal tubules. Abnormal PTH production in hypoparathyroidism disrupts this delicate balance.

Hypoparathyroidism may be acute or chronic and is classified as idiopathic, acquired, or reversible. The idiopathic and reversible forms are most common in children, and the clinical effects are usually correctable with replacement therapy. The acquired form, which is irreversible, is most common in older patients who have undergone thyroid gland surgery.

Causes

Idiopathic hypoparathyroidism may result from an autoimmune genetic disorder or the congenital absence of the parathyroid glands.

Acquired hypoparathyroidism typically results from accidental removal of or injury to one or more parathyroid glands during thyroidectomy or other neck surgery. It may also result from ischemic infarction of the parathyroid glands during surgery, hemochromatosis, sarcoidosis, amyloidosis, tuberculosis, neoplasms, trauma, or massive thyroid irradiation (rare).

Reversible hypoparathyroidism may result from hypomagnesemia-induced impairment of hormone secretion, from suppression of normal gland function due to hypercalcemia, or from delayed maturation of parathyroid function.

Complications

In hypoparathyroidism, complications are related to hypocalcemia. Decreased calcium levels can cause neuromuscular excitability and delayed cardiac repolarization, which may lead to heart failure. Lens calcification leads to cataract formation that may persist despite calcium replacement therapy. Papillary edema and increased intracranial pressure, irreversible calcification of basal ganglia, and bone deformities also occur. Laryngospasm, respiratory stridor, anoxia, paralysis of the vocal cords, seizures, and death may occur in severe cases of tetany. Hypoparathyroidism that develops during childhood results in malformed teeth.

Assessment findings

The patient's history may reveal neck surgery or irradiation or long-term hypomagnesemia from GI malabsorption or alcoholism.

The patient may report symptoms that reflect altered neuromuscular irritability. Acute (overt) tetany begins with a tingling in the fingertips, around the mouth and, occasionally, in the feet. The tingling spreads and becomes more severe, producing muscle tension and spasms. Pain varies with the degree of muscle tension but rarely affects the face, legs, and feet. The patient may also complain of his throat feeling constricted and of dysphagia. In chronic tetany, the patient may report difficulty in walking and a tendency to fall.

The patient may also complain of nausea, vomiting, abdominal pain, constipation or diarrhea, and personality changes, ranging from irritability and anxiety to depression, delirium, and frank psychosis.

On inspection, you may find dry skin, brittle hair, alopecia, transverse and longitudinal ridges in the fingernails, loss of eyelashes and fingernails, and stained, cracked, and decayed teeth from weakened enamel. During a tetany episode, you may observe that the hands, forearms and, less commonly, the feet may contort in a specific pattern, with thumb adduction followed by metacarpophalangeal joint flexion, interphalangeal joint extension, and wrist and elbow joint flexion.

Palpation may elicit Chvostek's and Trousseau's signs, which indicate latent tetany. (See [Eliciting signs of hypocalcemia](#).) Chvostek's sign may appear in other disorders, but only a hypocalcemic patient exhibits Trousseau's sign. You may also palpate increased deep tendon reflexes resulting from neuromuscular irritability.

Auscultation of the apical pulse may reveal cardiac arrhythmias.

Diagnostic tests

Radioimmunoassay for PTH shows diminished serum PTH concentration. Blood and urine tests reveal decreased serum and urine calcium levels, increased serum phosphate levels (more than 5.4 mg/dl), and reduced urine creatinine levels. X-rays indicate greater bone density and malformation. Electrocardiogram (ECG) changes disclose increased QT and ST intervals due to hypocalcemia.

Treatment

Because calcium absorption from the small intestine depends on the presence of activated vitamin D, treatment initially includes vitamin D, with or without supplemental calcium. Such therapy is usually lifelong, except in patients with reversible hypoparathyroidism. If the patient can't tolerate vitamin D because of hepatic or renal problems, calcitriol may be used.

Acute, life-threatening tetany calls for immediate I.V. administration of 10% calcium gluconate, 10% calcium gluceptate, or 10% calcium chloride to raise ionized serum calcium levels. Sedatives and anticonvulsants may control muscle spasms until calcium levels rise. Chronic tetany calls for maintenance of serum calcium levels with oral calcium supplements.

Nursing diagnoses

- u Altered thought processes u Anxiety u Body image disturbance u Decreased cardiac output u Impaired skin integrity u Ineffective breathing pattern u Ineffective individual coping u Knowledge deficit

Key outcomes

- u The patient's cardiac output will remain normal.
- u The patient's vital signs will remain stable.
- u The patient will maintain adequate ventilation.

- u The patient's skin integrity will remain intact.
- u The patient and family members will verbalize understanding of the disorder and treatment regimen.

Nursing interventions

- u Maintain a patent I.V. line. Keep emergency equipment available, including I.V. calcium gluconate and calcium chloride, an airway, a tracheotomy tray, and an endotracheal tube. If the patient receives I.V. calcium, assess the site for irritation. Maintain seizure precautions.
- u Monitor serum calcium and phosphorus levels.

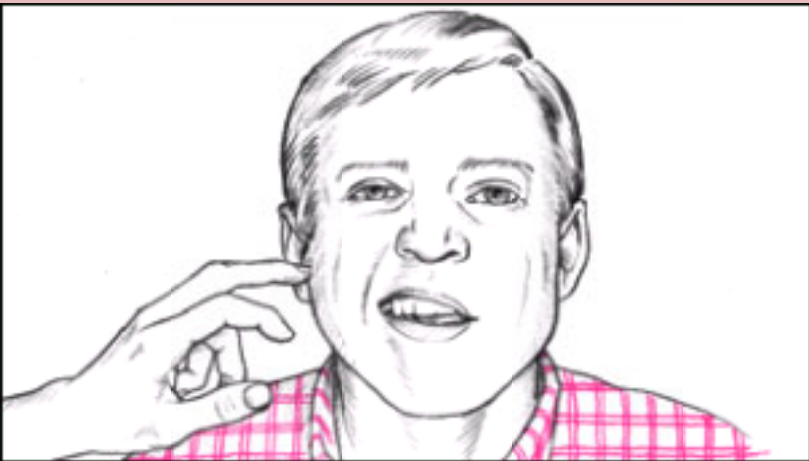

Eliciting signs of hypocalcemia

When your patient complains of muscle spasms and paresthesia in his limbs, try eliciting Chvostek's and Trousseau's signs —indications of tetany associated with calcium deficiency.

Follow the procedures described below, keeping in mind the discomfort they typically cause. If you detect these signs, notify the doctor immediately. During these tests, watch the patient for laryngospasm, monitor his cardiac status, and have resuscitation equipment nearby.

Chvostek's sign

To elicit this sign, tap the patient's facial nerve just in front of the earlobe and below the zygomatic arch or between the zygomatic arch and the corner of the mouth, as shown below.

A positive response (indicating latent tetany) ranges from simple mouth-corner twitching to twitching of all facial muscles on the side tested. Simple twitching may be normal in some patients. However, a more pronounced response usually confirms Chvostek's sign.

Trousseau's sign

In this test, occlude the brachial artery by inflating a blood pressure cuff on the patient's upper arm to a level between diastolic and systolic blood pressure. Maintain this inflation for 3 minutes while observing the patient for carpal spasm (shown above), which is Trousseau's sign.

- u Monitor the patient's ECG for increasing changes in QT intervals, heart block, and signs of decreasing cardiac output. Closely monitor the patient receiving both a digitalis glycoside and calcium because calcium potentiates the effect of digitalis glycosides. Stay alert for signs of digitalis toxicity (arrhythmias, nausea, fatigue, and vision changes).

HOME CARE

Living with hypoparathyroidism

To help your patient learn to live with hypoparathyroidism, follow these guidelines:

- u Tell the patient to take calcium supplements with or after meals and to chew the tablets well. Instruct him to always wear a medical identification bracelet and carry his medication with him at all times.
- u Teach the patient and his family to identify and report signs and symptoms of hypercalcemia, tetany, and respiratory distress.
- u Teach the patient techniques for decreasing stress and avoiding fatigue.
- u Advise the patient to follow a high-calcium, low-phosphorus diet. Discuss high-calcium foods, including dairy products, salmon, egg yolks, shrimp, and green, leafy vegetables. Caution him to avoid high-phosphate foods, such as spinach, rhubarb, and asparagus.

- u Hyperventilation, which may stem from anxiety during a tetany episode, can worsen tetany. So can recent blood transfusions because anticoagulant in stored blood binds calcium. Keep the patient calm and give him a sedative, if prescribed. Help the patient with mild tetany to rebreathe his own exhaled air by breathing into a paper bag.
- u Provide meticulous skin care. Use alcohol-free skin care products and an emollient lotion after bathing.
- u Institute safety precautions to minimize the risk of injury from falls. Provide support for walking.
- u Encourage the patient to verbalize his feelings about body image changes and rejection by others. Offer emotional support, and help him identify his strengths and use them to develop coping strategies. Refer him to a mental health professional for additional counseling, if necessary.

Patient teaching

- u Stress the importance of long-term management and follow-up care, especially periodic checks of serum calcium levels. (See [Living with hypoparathyroidism](#).)
- u Advise the patient that long-term replacement therapy is necessary. Instruct him to take the medication as ordered and not to discontinue it abruptly.

Adrenal disorders

The adrenal glands produce steroid hormones, epinephrine, and norepinephrine. Hyposecretion or hypersecretion of these substances results in a variety of serious disorders with complications ranging from psychiatric and sexual problems to coma and death.

ADRENAL HYPOFUNCTION

Adrenal hypofunction (also called adrenal insufficiency) has primary and secondary forms. Primary adrenal hypofunction (Addison's disease) originates within the adrenal gland and is characterized by decreased mineralocorticoid, glucocorticoid, and androgen secretion. Addison's disease is a relatively uncommon disorder that occurs in people of all ages and both sexes.

Adrenal hypofunction can also occur secondary to a disorder outside the gland (such as pituitary tumor with corticotropin deficiency), but aldosterone secretion may continue intact. With early diagnosis and adequate replacement therapy, the prognosis for both primary and secondary adrenal hypofunction is good.

Adrenal crisis—also called addisonian crisis—is a critical deficiency of mineralocorticoids and glucocorticoids. Adrenal crisis is a medical emergency that necessitates immediate, vigorous treatment. (See [How adrenal crisis develops](#).)

Causes

Addison's disease occurs when more than 90% of the adrenal gland is destroyed. Such massive destruction usually results from an autoimmune process in which circulating antibodies react specifically against the adrenal tissue.

Other causes include tuberculosis, bilateral adrenalectomy, hemorrhage into the adrenal gland, neoplasms, and infections, such as human immunodeficiency virus, histoplasmosis, meningococcal pneumonia, and cytomegalovirus. Rarely, a familial tendency toward autoimmune disease predisposes a patient to Addison's disease and to other endocrinopathies.

Secondary adrenal hypofunction that results in glucocorticoid deficiency can stem from hypopituitarism, which can cause decreased corticotropin secretion. It also can stem from abrupt withdrawal of long-term corticosteroid therapy, as when long-term exogenous corticosteroid stimulation suppresses pituitary corticotropin secretion and causes adrenal gland atrophy. In addition, it can result from removal of a nonendocrine, corticotropin-secreting tumor.

PATHOPHYSIOLOGY

How adrenal crisis develops

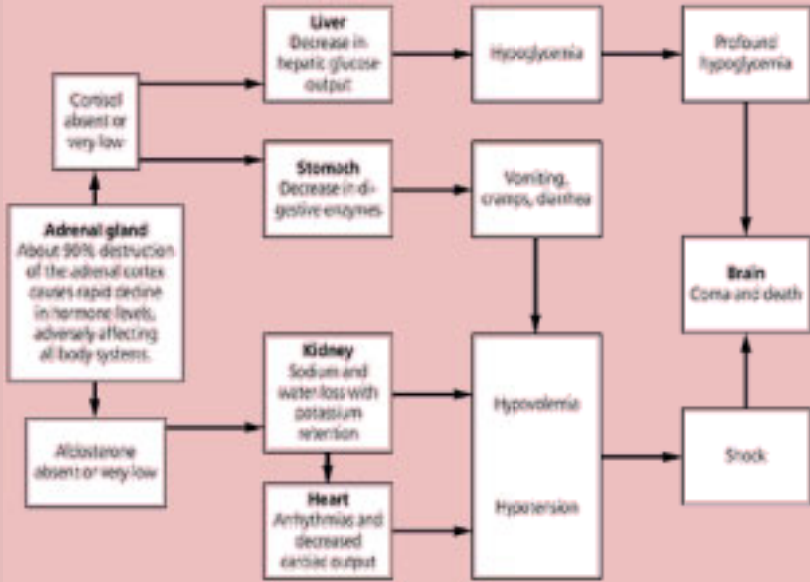

Adrenal crisis is the most serious complication of adrenal hypofunction. It can occur gradually or with catastrophic suddenness, making prompt emergency treatment essential. It's also known as acute adrenal insufficiency.

This potentially lethal condition usually develops in a patient who doesn't respond to hormone replacement therapy, undergoes marked stress without adequate glucocorticoid replacement, or abruptly stops hormonal therapy. It can also result from trauma, bilateral adrenalectomy, or adrenal gland thrombosis after a severe infection (Waterhouse-Friderichsen syndrome).

Signs and symptoms

In adrenal crisis, signs and symptoms include profound weakness, fatigue, nausea, vomiting, hypotension, dehydration and, occasionally, high fever followed by hypothermia. If untreated, this condition can ultimately cause vascular collapse, renal shutdown, coma, and death.

The flowchart below summarizes what happens in adrenal crisis and pinpoints its warning signs and symptoms.

Adrenal crisis occurs in a patient with adrenal hypofunction when trauma, surgery, or other severe physiologic stress completely exhausts the body's stores of glucocorticoids.

Complications

Adrenal crisis is the most serious complication of adrenal hypofunction.

Assessment findings

The history of a patient with adrenal hypofunction may reveal synthetic steroid use, adrenal surgery, or recent infection. The patient may complain of muscle weakness, fatigue, light-headedness when rising from a chair or bed, weight loss, cravings for salty food, decreased tolerance for even minor stress, and various GI disturbances, such as nausea, vomiting, anorexia, and chronic diarrhea. He may also complain of anxiety, irritability, and confusion. He may experience reduced urine output and other symptoms of dehydration. Women may have decreased libido resulting from reduced androgen production and amenorrhea.

On inspection, you may detect poor coordination, dry skin and mucous membranes related to dehydration, and decreased axillary and pubic hair in women. The patient with Addison's disease typically has a conspicuous bronze coloration of the skin that resembles a deep suntan, especially in the creases of the hands and over the metacarpophalangeal joints, elbows, and knees. The patient may also exhibit a darkening of scars, areas of vitiligo (an absence of pigmentation), and increased pigmentation of the mucous membranes, especially the buccal mucosa.

This abnormal coloration results from decreased secretion of cortisol (one of the glucocorticoids), which causes the pituitary gland to simultaneously secrete excessive amounts of melanocyte-stimulating hormone (MSH) and corticotropin. Secondary adrenal hypofunction doesn't cause hyperpigmentation because corticotropin and MSH levels are low.

On palpation, you may note a weak, irregular pulse. Auscultation of the patient's blood pressure demonstrates hypotension.

Diagnostic tests

Diagnosis of this disorder requires demonstration of decreased corticosteroid concentrations in plasma and an accurate classification of adrenal hypofunction as primary or secondary. Plasma cortisol levels and the corticotropin stimulation test are used to diagnose adrenal hypofunction.

Plasma cortisol levels confirm adrenal insufficiency. If secondary adrenal hypofunction is suspected, metyrapone is given I.V. or orally to stimulate the release of corticotropin. In Addison's disease, the hypothalamic-pituitary system responds normally and plasma reveals high levels of corticotropin. However, because adrenal glands are destroyed, plasma levels of cortisol precursor and urinary concentrations of 17-hydroxycorticosteroids don't increase. If either primary or secondary adrenal hypofunction is suspected, a corticotropin stimulation test is indicated.

u Corticotropin stimulation test demonstrates plasma cortisol response to corticotropin. After obtaining plasma cortisol samples and 24-hour urine cortisol levels, an I.V. infusion of corticotropin is administered over 6 to 8 hours. In Addison's disease, plasma and urine cortisol levels fail to increase normally in response to corticotropin. In secondary hypofunction, repeated doses of corticotropin over successive days produce a gradual increase in cortisol levels until normal levels are reached.

In a patient with typical symptoms of Addison's disease, the following laboratory findings strongly suggest acute adrenal insufficiency:

- u Plasma cortisol levels are decreased (less than 10 µl/dl in the morning, with lower levels in the evening). This test is time-consuming; crisis therapy shouldn't be delayed by waiting for results.
- u Serum sodium levels are reduced.
- u Serum potassium, serum calcium, and blood urea nitrogen levels are increased.
- u Hematocrit, lymphocyte, and eosinophil counts are elevated.
- u In addition, X-rays may show a small heart and adrenal calcification.

Treatment

Lifelong corticosteroid replacement is the main treatment for all patients with primary or secondary adrenal hypofunction. In general, cortisone or hydrocortisone (which have a mineralocorticoid effect) are given. Patients with Addison' disease may also need fludrocortisone, a synthetic drug that acts as a mineralocorticoid, to prevent dangerous dehydration and hypotension. Women with Addison's disease who have muscle weakness and decreased libido may benefit from testosterone injections but risk unfortunate masculinizing effects.

Treatment for a patient in adrenal crisis is prompt I.V. bolus administration of 100 mg of hydrocortisone, followed by 50 to 100 mg dose I.M. or diluted with dextrose in normal saline solution and given I.V. until the patient's condition stabilizes. Up to 300 mg/day of hydrocortisone and 3 to 5 L of I.V. normal saline solution may be required during the acute stage. With proper treatment, the crisis usually subsides quickly, with blood pressure stabilizing and water and sodium levels returning to normal. After the crisis, maintenance doses of hydrocortisone preserve physiologic stability.

Nursing diagnoses

- u Activity intolerance
- u Altered nutrition: Less than body requirements
- u Body image disturbance
- u Fluid volume deficit
- u Ineffective individual coping
- u Knowledge deficit
- u Risk for altered body temperature
- u Risk for impaired skin integrity
- u Risk for infection
- u Sexual dysfunction

Key outcomes

- u The patient's vital signs will remain stable.
- u The patient's fluid volume will remain within normal parameters.
- u The patient's temperature will remain within normal range.
- u The patient will remain free from signs and symptoms of infection.
- u The patient's skin integrity will remain intact.
- u The patient will exhibit increased energy tolerance without signs of fatigue.
- u The patient will express feelings about altered body image.
- u The patient will develop adequate coping skills.
- u The patient will express positive feelings about self.

Nursing interventions

- u In adrenal crisis, monitor vital signs carefully, especially for hypotension, volume depletion, and other signs of shock. Check for decreased level of consciousness and reduced urine output, which may also signal shock. Monitor for hyperkalemia before treatment and for hypokalemia afterward (from excessive mineralocorticoid effect). Check for cardiac arrhythmias.
- u If the patient also has diabetes mellitus, check blood glucose levels periodically because steroid replacement may necessitate adjustment of the insulin dosage.
- u Record weight and intake and output carefully because the patient may have volume depletion. Until onset of mineralocorticoid effect, force fluids to replace excessive fluid loss.

For patients on maintenance steroid therapy:

- u Control the environment to prevent stress. Encourage the patient to use relaxation techniques. Plan rest periods during the day, gradually increasing activities according to the patient's tolerance.
- u Encourage the patient to dress in layers to retain body heat, and adjust room temperature, if possible.
- u Provide good skin care. Use alcohol-free skin care products and an emollient lotion after bathing. Turn and reposition the bedridden patient every 2 hours. Avoid pressure over bony prominences.
- u Use protective measures to minimize the risk of infection. Provide a private room and reverse isolation if necessary. Limit the patient's visitors, especially those with infectious conditions. Use meticulous hand-washing technique.
- u Consult with a dietitian to plan a diet that maintains sodium and potassium balances and provides adequate protein and carbohydrates. If the patient is anorexic, suggest that he eat six small meals a day to increase calorie intake.
- u If the patient is receiving steroids, watch for cushingoid signs, such as fluid retention around the eyes and face. Monitor fluid and electrolyte balance, especially if the patient is receiving mineralocorticoids. Monitor weight and check blood pressure to assess body fluid status. Remember, steroids administered in the late afternoon or evening may cause central nervous system stimulation and insomnia in some patients. Check for petechiae because these patients bruise easily.
- u In women receiving testosterone injections, watch for and report facial hair growth and other signs of masculinization. Dosage adjustment may be needed.
- u If the patient is receiving only glucocorticoids, observe for orthostatic hypotension or abnormal serum electrolyte levels, which may indicate a need for mineralocorticoid therapy.

- u Encourage the patient to verbalize his feelings about body image changes and sexual dysfunction. Discuss fear of rejection by others, and offer emotional support. Help him to develop coping strategies. Refer him for additional counseling, if necessary

Patient teaching

- u Explain that lifelong steroid therapy is necessary. Teach the patient and family members to identify and report signs and symptoms of drug overdose (weight gain and edema) or underdose (fatigue, weakness, and dizziness).
- u Advise the patient that he needs to increase the dosage during times of stress (when he has a cold, for example). Warn that infection, injury, or profuse sweating in hot weather can precipitate adrenal crisis. Caution him not to withdraw the medication suddenly because this can also cause adrenal crisis.
- u Instruct the patient always to carry a medical identification card stating that he takes a steroid and giving the name and dosage of the drug. Teach him and family members how to give an injection of hydrocortisone and advise them to keep an emergency kit available containing a prepared syringe of hydrocortisone to use in times of stress.
- u Instruct the patient to take steroids with antacids or meals to minimize gastric irritation. Suggest taking two-thirds of the dosage in the morning and the remaining one-third in the early afternoon to mimic diurnal adrenal secretion.
- u Inform the patient and family members that the disease causes mood swings and changes in mental status, which steroid replacement therapy can correct.
- u Review protective measures to decrease stress and help prevent infections. For example, the patient should get adequate rest, avoid fatigue, eat a balanced diet, and avoid people with infectious conditions. Also be sure to provide instructions for stress management and relaxation techniques.

ADRENOGENITAL SYNDROME

Excessive production of adrenal androgens causes adrenogenital syndrome, resulting in masculinization, virilization, and hermaphrodisism. In rare, true hermaphrodisism the person has both ovarian and testicular tissues, a uterus, and ambiguous gonads distributed in various patterns. Adrenogenital syndrome may be inherited (congenital adrenal hyperplasia [CAH]) or acquired (adrenal virilism), usually as a result of an adrenal tumor. (See [Acquired adrenal virilism.](#))

CAH is the most common adrenal disorder in infants and children; simple virilizing CAH and salt-losing CAH are the most common forms. Adrenal virilism is rare and affects females twice as often as males.

Causes and pathophysiology

CAH is transmitted as an autosomal recessive trait that causes deficiencies in the enzymes needed for adrenocortical secretion of cortisol and, possibly, aldosterone. Compensatory secretion of corticotropin produces varying degrees of adrenal hyperplasia.

In simple virilizing CAH, deficiency of the enzyme 21-hydroxylase results in underproduction of cortisol. In turn, this cortisol deficiency stimulates increased secretion of corticotropin, producing large amounts of cortisol precursors and androgens that don't require 21-hydroxylase for synthesis.

In salt-losing CAH, 21-hydroxylase is almost completely absent. Corticotropin secretion increases, causing excessive production of cortisol precursors, including salt-wasting compounds. Plasma cortisol levels and aldosterone—both dependent on 21-hydroxylase—decrease precipitously and, in combination with the excessive production of salt-wasting compounds, expedite acute adrenal crisis. Corticotropin hypersecretion stimulates adrenal androgens, possibly even more than in simple virilizing CAH, and produces masculinization.

Other rare CAH enzyme deficiencies exist and lead to increased or decreased production of affected hormones.

Complications

Unless salt-losing CAH is treated promptly, dehydration and hyperkalemia may lead to cardiovascular collapse and cardiac arrest in neonates. Other complications of adrenogenital syndrome include hypertension, hyperkalemia, infertility, adrenal tumor, tendency to develop adrenal crisis (from stress), and altered growth, external genitalia, and sexual maturity.

Assessment findings

Varying assessment findings depend on the cause of the disorder and the patient's age and sex. Suspect CAH in infants hospitalized for failure to thrive, dehydration, or diarrhea, as well as in tall, sturdy-looking children with a history of episodic illnesses.

Inspection of the female neonate with simple virilizing CAH finds ambiguous genitalia (enlarged clitoris with urethral opening at the base and some labioscrotal fusion) but a normal genital tract and gonads. Inspection of an older female child with simple virilizing CAH reveals signs of progressive virilization: early appearance of pubic and axillary hair, deep voice, acne, and facial hair. The patient's history includes failure to begin menstruation.

On inspection, the male neonate with simple virilizing CAH has no obvious abnormalities. At prepuberty, the child shows accentuated masculine characteristics, such as a deepened voice, an enlarged phallus, and frequent erections. At puberty, male patients have small testes.

Both males and females with this condition may be taller than other children their age due to rapid bone and muscle growth, but because excessive androgen levels hasten epiphyseal closure, they may exhibit abnormally short adult stature.

Parents of an infant with salt-losing CAH may disclose that the child is apathetic, fails to eat, and has diarrhea. Without prompt treatment, the infant may develop fatal adrenal crisis in the first week of life (vomiting, dehydration from hyponatremia, and hyperkalemia).

Inspection of the older female with salt-losing CAH reveals more complete virilization than in the simple form, including even the development of male external genitalia without testes. The male child with this condition has no external genital abnormalities.

Diagnostic tests

The following test findings are needed to confirm adrenogenital syndrome:

- u elevated levels of urine 17-ketosteroids (17-KS), which can be suppressed by administering oral dexamethasone
- u increased urine metabolites of hormones, particularly pregnanetriol
- u elevated levels of plasma 17-hydroxyprogesterone and dehydroepiandrosterone sulfate
- u hyperkalemia, hyponatremia, and hypochloremia in the presence of elevated levels of urine 17-KS and pregnanetriol and decreased aldosterone levels, which confirm salt-losing CAH in any infant with signs and symptoms of adrenal hypofunction or adrenal crisis in the first week after birth.

Ambiguous external genitalia suggest hermaphrodisism; a gonadal biopsy and chromosomal studies are needed to confirm the diagnosis.

Treatment

Simple virilizing CAH necessitates correction of the cortisol deficiency and inhibition of excessive pituitary corticotropin production. This is accomplished through daily administration of cortisone or hydrocortisone. Such treatment returns androgen production to normal levels. Initially, the oral hydrocortisone dosage starts at 25 to 30 mg/m²/day. Then, the dosage is reduced to 10 to 20 mg/m²/day. Infants must receive I.M. cortisone or hydrocortisone until age 18 months; after that, they may take the drug orally.

The infant with salt-losing CAH in adrenal crisis requires immediate I.V. sodium chloride and glucose infusion to maintain fluid and electrolyte balance and to stabilize

vital signs. If this treatment doesn't control symptoms while diagnosis is being established, I.M. desoxycorticosterone and, occasionally, I.V. hydrocortisone are necessary. Later, maintenance therapy includes mineralocorticoid (desoxycorticosterone) and glucocorticoid (cortisone or hydrocortisone) replacement.

Based on the anatomy of the external genitalia and chromosomal evaluation, sexual assignment and reconstructive surgery may be recommended. For example, the female with masculine external genitalia requires reconstructive surgery such as correction of the labial fusion and of the urogenital sinus. Such surgery is usually scheduled between ages 1 and 3 after the effect of cortisone therapy has been assessed.

Nursing diagnoses

- u Altered growth and development
- u Body image disturbance
- u Ineffective family coping
- u Ineffective individual coping
- u Knowledge deficit
- u Risk for fluid volume deficit

ADVANCED PRACTICE

Acquired adrenal virilism

Acquired adrenal virilism results from virilizing adrenal tumors, carcinomas, or adenomas.

Clinical effects

Although acquired adrenal virilism can develop at any age, its clinical effects vary with the patient's age at onset:

- u prepubescent girls—pubic hair, clitoral enlargement; at puberty, no breast development, menses delayed or absent
- u prepubescent boys—hirsutism, macrogenitosomia precox (excessive body development with marked enlargement of genitalia). Occasionally, the penis and prostate equal those of an adult male in size; however, testicular maturation fails to occur.
- u women (especially middle-aged)—dark hair on legs, arms, chest, back, and face; pubic hair extending toward navel; oily skin, sometimes with acne; menstrual irregularities; muscular hypertrophy (masculine resemblance); male pattern baldness; and atrophy of breasts and uterus
- u men—no overt signs; discovery of tumor is usually accidental
- u all patients—good muscular development, taller than average during childhood and adolescence, short stature as adults due to early closure of epiphyses.

Diagnostic tests

- u Urine total 17-ketosteroids (17-KS): greatly elevated levels, which vary daily; oral dexamethasone doesn't suppress 17-KS.
- u Dehydroepiandrosterone: plasma levels greatly elevated
- u Serum electrolyte levels: normal
- u X-ray of kidneys: may show downward displacement of kidneys by tumor

Treatment

The patient undergoes surgical excision of the tumor and metastases (if present) when possible, or radiation therapy and chemotherapy. Preoperative treatment may include glucocorticoids. With treatment, the prognosis is very good in patients with slow-growing, nonrecurring tumors. Levels of 17-hydroxyprogesterone, androstenedione, testosterone, and renin are measured to monitor therapy.

Key outcomes

- u The patient's vital signs will remain stable.
- u The patient's intake will equal his output.
- u The patient's laboratory values will return to normal.
- u The patient will avoid complications.
- u The patient and family members will express understanding of the disorder and treatment modality.

Nursing interventions

- u When caring for an infant with adrenal crisis, keep the I.V. line patent, infuse fluids, and give steroids as ordered. Monitor body weight, vital signs, respiratory status, urine output, and serum electrolyte levels.
- u Provide protective measures to minimize external stress. Limit visitors, provide a private room, and decrease environmental stimuli.
- u Monitor the patient receiving desoxycorticosterone for edema, weakness, and hypertension. Be alert for significant weight gain and rapid changes in height because normal growth is an important indicator of adequate therapy.
- u Encourage the parents and the older child to verbalize their feelings about altered body image and fear of rejection by others. Offer a positive, but realistic, assessment of the patient's condition. Assist the parents and child to identify strengths and use them to develop coping strategies. Refer family members to a mental health counselor, if necessary.

Patient teaching

- u Teach the parents of an infant with adrenogenital syndrome about normal growth and development and how their child may differ. Correct misconceptions about the disorder and explain treatment options. Explain how the choice of sexual assignment is made and how abnormalities are surgically corrected. Refer family members to a genetic specialist for counseling.
- u Advise the parents and child that long-term steroid therapy is necessary. Warn them not to discontinue steroids abruptly to prevent potentially fatal adrenal insufficiency.
- u Teach the patient and family members to identify and report signs of drug overdose and underdose, stress, and infection, which may require altered steroid dosages.
- u Instruct the patient to wear a medical identification bracelet indicating that she's receiving prolonged steroid therapy and providing information about dosage.
- u Stress the importance of continued medical follow-up throughout the child's life.

CUSHING'S SYNDROME

Cushing's syndrome is the clinical manifestation of glucocorticoid (particularly cortisol) excess. Excess secretions of mineralocorticoids and androgens may also cause Cushing's syndrome. The disorder is classified as primary, secondary, or iatrogenic, depending on its etiology. It's most common in females.

The unmistakable signs of Cushing's syndrome include adiposity of the face, neck, and trunk, and purple striae on the skin. The prognosis depends on early diagnosis, identification of the underlying cause, and effective treatment.

Causes

In about 70% of patients, Cushing's syndrome results from excess production of corticotropin and consequent hyperplasia of the adrenal cortex. Corticotropin overproduction may stem from pituitary hypersecretion (Cushing's disease), a corticotropin-producing tumor in another organ (especially bronchogenic or pancreatic carcinoma), or administration of synthetic glucocorticoids or corticotropin. In the remaining 30% of patients, Cushing's syndrome results from a cortisol-secreting

adrenal tumor, which is usually benign. In infants, the usual cause of Cushing's syndrome is adrenal carcinoma. (See [Understanding corticosteroid excess.](#))

Complications

The stimulating and catabolic effects of cortisol produce the complications of Cushing's syndrome. Increased calcium resorption from bone may lead to osteoporosis and pathologic fractures. Peptic ulcer may result from increased gastric secretions, pepsin production, and decreased gastric mucus. Dyslipidosis usually occurs. Increased hepatic gluconeogenesis and insulin resistance can cause impaired glucose tolerance. Overt diabetes mellitus occurs in fewer than 10% of patients.

Frequent infections or slow wound healing due to decreased lymphocyte production and suppressed antibody formation may occur. Suppressed inflammatory response may mask even a severe infection.

Hypertension due to sodium and water retention is common and may lead to ischemic heart disease and heart failure. Menstrual disturbances and sexual dysfunction also occur. Decreased ability to handle stress may result in psychiatric problems, ranging from mood swings to frank psychosis.

PATHOPHYSIOLOGY

Understanding corticosteroid excess

The following are possible causes of corticosteroid excess in Cushing's syndrome.

Altered protein metabolism

Excessive catabolism of proteins leads to loss of muscle mass with various consequences including:

- muscle wasting of extremities; arms and legs become thin
- difficulty pulling up from low chairs and climbing stairs
- generalized weakness and fatigue
- loss of protein bone matrix leading to osteoporosis; compression fractures of spine; complaints of backache, bone pain, and pathological fractures
- loss of collagen support to skin causing thin, fragile skin; purple striae seen following rapid weight gain; skin bruising easily
- delayed wound healing.

Altered fat metabolism

Alterations in fat metabolism lead to obesity and abnormal fat distribution.

- Moon face is seen from fatty deposits in cheeks and face.
- Buffalo hump occurs as a result of intracapsular fat deposits in upper back.
- Truncal obesity is seen from mesenteric fat deposits.
- Weight gain is usually experienced.

Altered carbohydrate metabolism

Increased cortisol levels stimulate hepatic gluconeogenesis and glycolysis.

- Postprandial hyperglycemia is a result of impaired insulin metabolism.
- Serum blood sugar levels are elevated.
- Steroid-induced diabetes mellitus may develop.

Altered water and mineral metabolism

Increased cortisol produces mineral corticoid activity.

- Sodium and water are retained, contributing to weight gain and edema.
- Hypertension may develop.
- Hypokalemia, hypochloremia, and alkalosis may be present.
- Increased calcium resorption from bone contributes to osteoporosis and can contribute to the formation of renal calculi.

Altered immune response

Increased cortisol causes a decrease in lymphocytes, especially T lymphocytes.

- Cell-mediated immunity is decreased.
- Neutrophils increase.
- Antibody activity is altered.
- Vulnerability to viral and fungal infections, especially opportunistic infections, increases.
- Early signs of infection, particularly fever, are masked.
- Wound healing is delayed.

Altered emotional stability

Elevated cortisol level contributes to varied mood states and affects mental abilities.

- Mood swings, euphoria, and depression may occur.
- Anxiety, irritability, and psychosis may occur.
- Difficulty concentrating and poor memory may occur.
- Sleep patterns may be altered and difficulty falling asleep may occur.

Altered hematologic activity

Excessive cortisol results in changes of many blood components.

- Red blood cells, hemoglobin, and hematocrit may be high. This may contribute to a facial plethora often seen in Cushing's disease.
- Leukocytosis, lymphopenia, and eosinopenia may occur.
- Increased platelets and clotting factors may contribute to thrombus formation.

Altered androgen activity

Excessive cortisol results in increased androgen production, leading to virilizing effects in females including:

- hirsutism —a downy covering of hair on face and body
- facial acne
- loss of scalp hair
- menstrual irregularities, including amenorrhea
- altered libido.

Assessment findings

The patient may report using synthetic steroids. She may complain of fatigue, muscle weakness, sleep disturbances, water retention, amenorrhea, decreased libido, irritability, and emotional instability. Additionally, the patient may list various signs and symptoms that resemble those of hyperglycemia.

Inspection may reveal a spectrum of characteristic signs and symptoms, including thin hair, a moon-shaped face, hirsutism, acne, a buffalo humplike back, and thin extremities from muscle wasting. Other observable features may include petechiae, ecchymoses, and purplish striae; delayed wound healing; and swollen ankles. Auscultation typically reveals hypertension.

Diagnostic tests

Diagnosis of Cushing's syndrome depends on a demonstrated increase in cortisol production and the failure to suppress endogenous cortisol secretion after administration of dexamethasone.

Initial screening may consist of a 24-hour urine test to determine free cortisol excretion rate and a low-dose dexamethasone test. Failure to suppress plasma and urine cortisol levels confirms the diagnosis of Cushing's syndrome.

A low-dose dexamethasone suppression test can be used to determine if Cushing's syndrome results from pituitary dysfunction (Cushing's disease). In this diagnostic test, dexamethasone suppresses plasma cortisol levels. Failure to suppress these levels indicates that the syndrome results from an adrenal tumor or a nonendocrine, corticotropin-secreting tumor. Urinary 17-hydroxycorticosteroids (17-OHCS) and 17-ketogenic steroids decrease to 50% or less of basal levels. Failure to suppress these levels indicates that the syndrome results from an adrenal tumor or a nonendocrine, corticotropin-secreting tumor. This test can produce false-positive results.

In a stimulation test, metyrapone—which blocks cortisol production by the adrenal glands—is administered to test the ability of the pituitary gland and the hypothalamus to detect and correct low levels of plasma cortisol by increasing corticotropin production. The patient with Cushing's disease reacts to this stimulus by secreting an excess of plasma corticotropin, measured by levels of urinary 17-OHCS. If the patient has an adrenal or a nonendocrine corticotropin-secreting tumor, the pituitary gland—which is suppressed by the high cortisol levels—can't respond normally, so steroid levels remain stable or decrease.

Radiologic evaluation for Cushing's syndrome is used to locate the causative tumor in the pituitary gland or the adrenals. Tests include ultrasonography, a computed tomography scan, magnetic resonance imaging, or angiography to locate tumors.

Blood chemistry may show hypernatremia, hypokalemia, hypocalcemia, and elevated blood glucose and lymphocyte counts.

Treatment

Management to restore hormone balance and reverse Cushing's syndrome may require radiation, drug therapy, or surgery.

A patient with pituitary-dependent Cushing's syndrome with adrenal hyperplasia may need hypophysectomy or pituitary irradiation. If hypophysectomy and irradiation are unsuccessful or infeasible, bilateral adrenalectomy may be performed. A patient with a nonendocrine corticotropin-producing tumor requires excision of the tumor, followed by drug therapy with mitotane, metyrapone, or aminoglutethimide to decrease cortisol levels if there are symptoms. Aminoglutethimide and ketoconazole decrease cortisol levels and have been beneficial for many cushingoid patients. Aminoglutethimide alone, or in combination with metyrapone, may also be useful in metastatic adrenal carcinoma.

Before surgery, the patient with cushingoid symptoms requires management to control hypertension, edema, diabetes, and cardiovascular manifestations and to prevent infection. Glucocorticoid administration on the morning of surgery can help prevent acute adrenal insufficiency during surgery. Cortisol therapy is essential during and after surgery to help the patient tolerate the physiologic stress imposed by removal of the pituitary or adrenal glands. If normal cortisol production resumes, steroid therapy may gradually be tapered and eventually discontinued. However, bilateral adrenalectomy or total hypophysectomy mandates lifelong steroid replacement therapy to correct hormonal deficiencies.

Nursing diagnoses

u Activity intolerance u Altered thought processes u Body image disturbance u Fluid volume excess u Impaired skin integrity u Ineffective individual coping u Knowledge deficit u Risk for infection u Risk for injury u Sexual dysfunction

Key outcomes

- u The patient's fluid volume will remain normal.
- u The patient's skin integrity will remain intact.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will perform activities of daily living as tolerated within the confines of the disorder.
- u The patient will express positive feelings about self.

Nursing interventions

- u Keep accurate records of vital signs, fluid intake, urine output, and weight. Monitor serum electrolyte levels daily.
- u Consult a dietitian to plan a diet high in protein and potassium and low in calories, carbohydrates, and sodium.
- u Use protective measures to reduce the risk of infection. If necessary, provide a private room and establish reverse isolation precautions. Use meticulous hand-washing technique.
- u Schedule activities around the patient's rest periods to avoid fatigue. Gradually increase activity as tolerated.
- u Institute safety precautions to minimize the risk of injury from falls. Help the patient walk to avoid bumps and bruises.
- u Help the bedridden patient turn and reposition herself every 2 hours. Use extreme caution while moving the patient to minimize skin trauma and bone stress. Provide frequent skin care, especially over bony prominences. Provide support with pillows and a convoluted foam mattress.
- u Encourage the patient to verbalize her feelings about body image changes and sexual dysfunction. Offer emotional support and a positive, realistic assessment of her condition. Help her to develop coping strategies. Refer her to a mental health professional for additional counseling, if necessary.

After bilateral adrenalectomy and hypophysectomy:

- u Monitor urine output and check vital signs carefully, watching for signs of hemorrhage and shock (decreased blood pressure, increased pulse rate, pallor, and cold, clammy skin). To counteract shock, give vasopressors and increase the rate of I.V. fluids as ordered. Because mitotane, aminoglutethimide, and metyrapone decrease mental alertness and produce physical weakness, assess neurologic and behavioral status and warn the patient of adverse central nervous system effects. Also watch for severe nausea, vomiting, and diarrhea.
- u Check laboratory reports for hypoglycemia due to removal of the source of cortisol, a hormone that maintains blood glucose levels.
- u Check for abdominal distention and return of bowel sounds after adrenalectomy.
- u Check regularly for signs of adrenal hypofunction (orthostatic hypotension, apathy, weakness, and fatigue), which indicate that steroid replacement is inadequate.
- u In the patient undergoing pituitary surgery, check for and immediately report signs of increased intracranial pressure (confusion, agitation, changes in level of consciousness, nausea, and vomiting). Monitor for signs of hypopituitarism and transient diabetes insipidus.

If the transsphenoidal approach is used to perform hypophysectomy, nursing care includes:

- u keeping the head of the bed elevated at least 30 degrees
- u maintaining nasal packing
- u assessing for signs of cerebrospinal fluid leak
- u performing special mouth care
- u preventing actions that increase intracranial pressure.

Patient teaching

- u Advise the patient that lifelong steroid replacement is necessary. Teach her and family members to identify and report signs of drug overdose (edema and weight gain) or underdose (fatigue, weakness, and dizziness). Warn her not to abruptly discontinue the drug because this may precipitate adrenal crisis.
- u Instruct the patient to take steroids with antacids or meals to minimize gastric irritation. Advise her to take two-thirds of a dose in the morning and the remaining third in the early afternoon to mimic diurnal adrenal secretion.
- u Encourage the patient to wear a medical identification bracelet and carry her medication with her at all times.
- u Teach the patient protective measures to decrease stress and infections. For example, she should get adequate rest and avoid fatigue, eat a balanced diet, and avoid people with infections. Also teach relaxation and stress-reduction techniques.

HYPERALDOSTERONISM

In hyperaldosteronism, hypersecretion of the mineralocorticoid aldosterone by the adrenal cortex causes excessive reabsorption of sodium and water and excessive renal excretion of potassium. (See [Effects of excessive aldosterone secretion.](#))

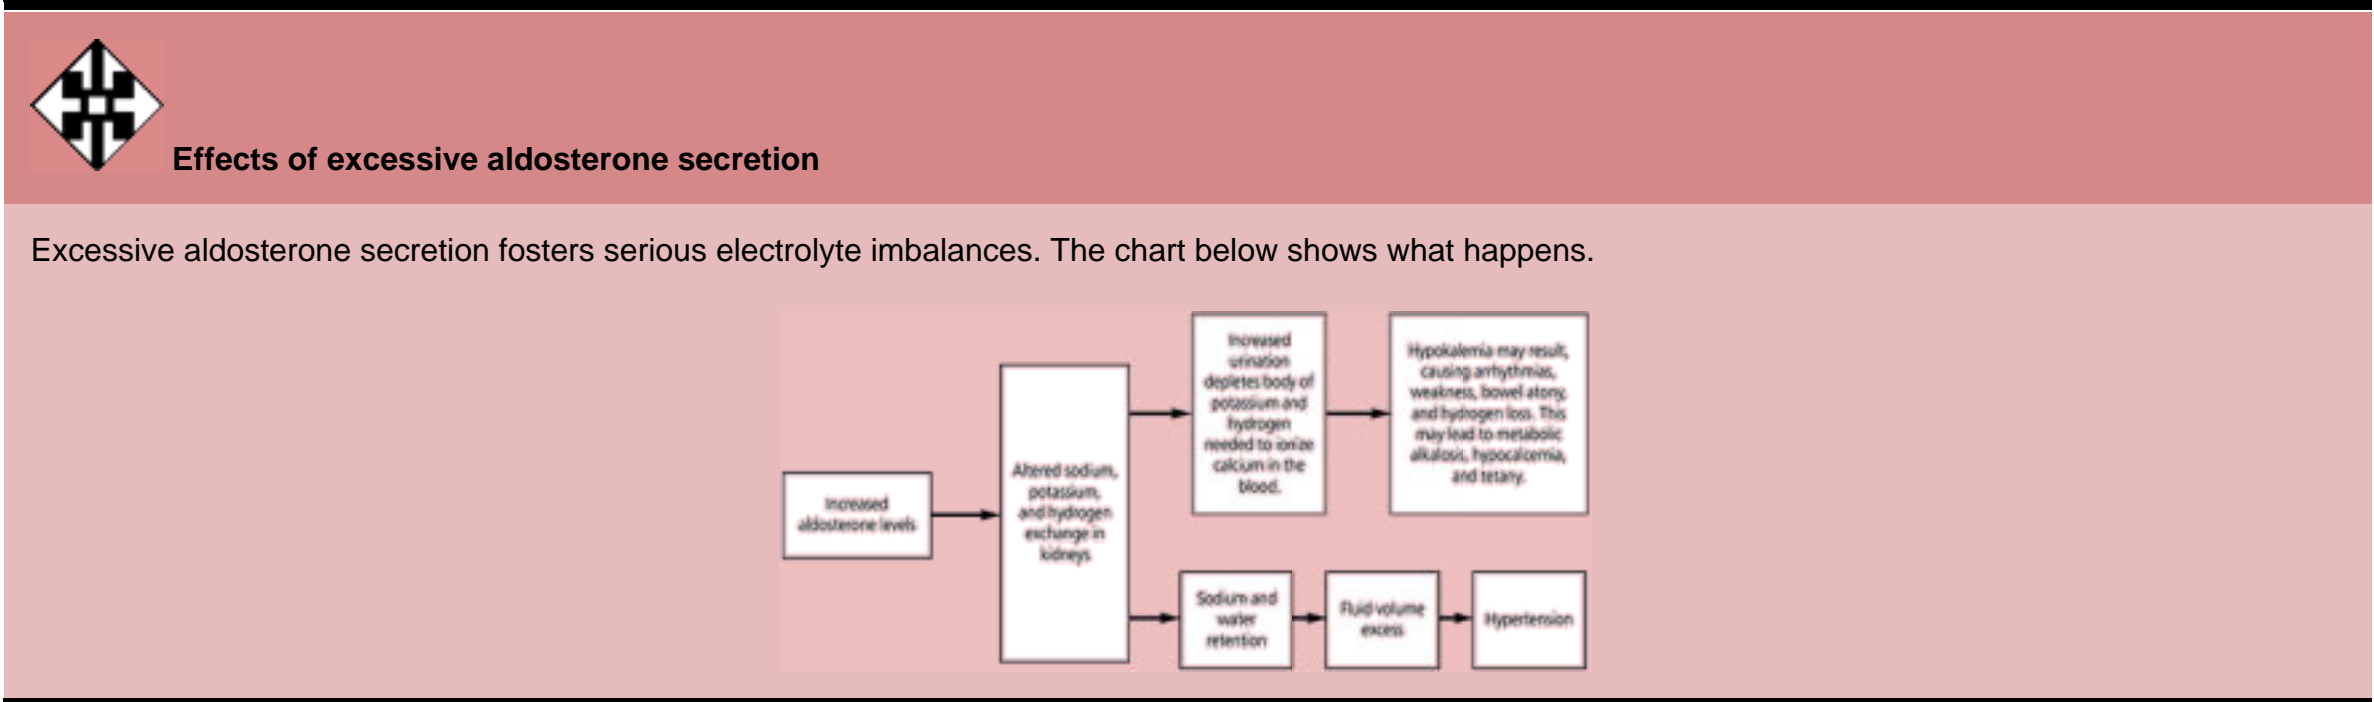

The disorder may be classified as primary, resulting from a stimulus inside the adrenal gland, or secondary, resulting from an extra-adrenal stimulus. Incidence of hyperaldosteronism is two times greater in women than in men and highest between ages 30 and 50.

Causes

Primary hyperaldosteronism (Conn's syndrome) is uncommon. In 70% of patients, it results from a small, unilateral aldosterone-producing adrenal adenoma. In the remaining 30%, the cause is either unclear, adrenocortical hyperplasia (in children), or carcinoma. Excessive ingestion of English black licorice or a similar substance can produce a syndrome similar to primary hyperaldosteronism due to the mineralocorticoid action of a type of acid found in licorice.

Secondary hyperaldosteronism results from extra-adrenal pathology, which stimulates the adrenal gland to increase production of aldosterone. For example, conditions that reduce renal blood flow (renal artery stenosis) and extracellular fluid volume or that produce a sodium deficit activate the renin-angiotensin system and, subsequently, increase aldosterone secretion. Thus, secondary hyperaldosteronism may result from conditions that induce hypertension through increased renin production (such as Wilms' tumor), from ingestion of oral contraceptives, and from pregnancy. Secondary hyperaldosteronism may also result from disorders unrelated to hypertension that may or may not cause edema. For example, nephrotic syndrome, hepatic cirrhosis with ascites, and heart failure commonly induce edema; Bartter's syndrome and salt-losing nephritis don't.

PATHOPHYSIOLOGY

Complications

Hyperaldosteronism can produce neuromuscular irritability, tetany, paresthesia, and seizures. Cardiac complications include arrhythmias, ischemic heart disease, left ventricular hypertrophy, heart failure, and death. Metabolic alkalosis, nephropathy, and azotemia may also occur.

Assessment findings

The patient may complain of headache, vision disturbances, muscle weakness, fatigue, polyuria, and polydipsia. Inspection may detect intermittent flaccid paralysis, resulting from hypokalemia and, possibly, tetany, which may be caused by metabolic alkalosis and lead to hypocalcemia. Secondary hyperaldosteronism rarely occurs without edema.

Palpation may reveal a weak pulse, signs of muscle tonicity, and positive Chvostek's and Trousseau's signs. Auscultation of the apical pulse may reveal cardiac arrhythmias. Auscultation of blood pressure discloses hypertension.

Diagnostic tests

A persistently low serum potassium level in a nonedematous patient who isn't taking diuretics, who doesn't have obvious GI losses (from diarrhea), and who has a normal sodium intake suggests hyperaldosteronism. If hypokalemia develops in a hypertensive patient shortly after starting treatment with potassium-wasting diuretics (such as thiazides) and it persists after the diuretic has been discontinued and potassium replacement therapy has been instituted, evaluation for hyperaldosteronism is necessary. The following test results confirm hyperaldosteronism:

- u A low plasma renin level after volume depletion by diuretic administration when the patient is sitting or standing and a high plasma aldosterone level after volume expansion by salt loading confirm primary hyperaldosteronism in a hypertensive patient without edema.
- u Elevated serum bicarbonate levels with ensuing alkalosis commonly results from hydrogen and potassium ion loss in the distal renal tubules.
- u Other test findings show markedly increased urine aldosterone levels, increased plasma aldosterone levels, and increased plasma renin levels (in secondary hyperaldosteronism).
- u A suppression test is used to differentiate between primary and secondary hyperaldosteronism. The patient receives oral desoxycorticosterone acetate for 3 days while plasma aldosterone levels and urine metabolites are continuously measured. These levels decrease in secondary hyperaldosteronism but remain the same in primary hyperaldosteronism. Simultaneously, renin levels are low in primary hyperaldosteronism and high in secondary hyperaldosteronism.
- u Other helpful diagnostic evidence includes increased plasma volume of 30% to 50% above normal; electrocardiogram signs of hypokalemia (ST-segment depression and U waves); chest X-ray showing left ventricular hypertrophy from chronic hypertension; and location of tumor shown on computed tomography scan,

ultrasonography, or magnetic resonance imaging.

Treatment

Treatment for primary hyperaldosteronism may include unilateral adrenalectomy, but hyperaldosteronism may be controlled without surgery through administration of the potassium-sparing diuretic spironolactone and sodium restriction. Bilateral adrenalectomy reduces blood pressure for most patients with idiopathic primary hyperaldosteronism. However, some degree of hypertension usually persists, requiring treatment with spironolactone or other antihypertensive drug. Such patients also require lifelong adrenal hormone replacement.

Treatment of secondary hyperaldosteronism must include correction of the underlying cause.

Nursing diagnoses

u Altered tissue perfusion u Altered urinary elimination u Decreased cardiac output u Ineffective individual coping u Knowledge deficit u Pain

Key outcomes

- u The patient's vital signs will remain stable.
- u The patient's cardiac output will remain normal.
- u The patient will express feelings of comfort.
- u The patient's intake will equal his output.
- u The patient will express understanding of the condition and treatment modalities.

Nursing interventions

- u Keep accurate records of the patient's vital signs, fluid intake, urine output, and weight.
- u Monitor serum electrolyte levels.
- u Watch for signs of tetany (muscle twitching and Chvostek's sign) and for hypokalemia-induced cardiac arrhythmias, paresthesia, or weakness. Give potassium replacement, as ordered, and keep I.V. calcium gluconate available.
- u Provide comfort measures to relieve headache: Administer analgesics, apply ice packs, and decrease environmental stimuli.
- u Consult a dietitian to plan a low-sodium, high-potassium diet.
- u Schedule activities to encourage rest, prevent fatigue, and decrease myocardial oxygen demand. Gradually increase activity as tolerated.
- u After adrenalectomy, monitor for weakness, hyponatremia, increasing serum potassium levels, and signs of adrenal insufficiency, especially hypotension.
- u Encourage the patient to verbalize her feelings about her illness. Offer emotional support, and help her identify her strengths and use them to develop coping strategies. Refer her to a mental health professional, if necessary.

Patient teaching

- u Advise the patient that she needs long-term adrenal hormone replacement. Tell her and family members to identify and report signs of drug overdose or underdose.
- u Encourage the patient to wear a medical identification bracelet and to carry her medications with her at all times.
- u Instruct the patient to follow a low-sodium, high-potassium diet.
- u If the patient is taking spironolactone, tell her to watch for and report signs of hyperkalemia. If the patient is a man, warn him that impotence and gynecomastia may follow long-term use.

PHEOCHROMOCYTOMA

Pheochromocytoma (also known as chromaffin tumor) is a rare disease, characterized by paroxysmal or sustained hypertension due to oversecretion of the catecholamines epinephrine and norepinephrine. By some estimates, about 0.5% of newly diagnosed patients with hypertension have pheochromocytoma; this tumor is usually benign but is malignant in a few patients.

Pheochromocytoma affects all races and both sexes and is typically familial. Although this disorder is potentially fatal, the prognosis is generally good with treatment.

Causes

Pheochromocytoma stems from a chromaffin cell tumor of the adrenal medulla or sympathetic ganglia, more commonly in the right adrenal gland than in the left. Extra-adrenal pheochromocytomas may be located in the abdomen, thorax, urinary bladder, and neck and in association with the 9th and 10th cranial nerves.

Pheochromocytoma may be inherited as an autosomal dominant trait.

Complications

Pheochromocytoma produces the same complications as those of severe, persistent hypertension: cerebrovascular accident (CVA), retinopathy, heart disease, and irreversible kidney damage. Often, the disorder is diagnosed during pregnancy when uterine pressure on the tumor induces more frequent attacks of hypertensive crisis. Such attacks can be fatal for both mother and fetus as a result of CVA, acute pulmonary edema, cardiac arrhythmias, or hypoxia. In such patients, the risk of spontaneous abortion is high, but most fetal deaths occur during labor or immediately after birth. Cholelithiasis is often associated with this disorder.

Patients with pheochromocytoma have an increased risk of serious complications and death during invasive diagnostic testing and surgery. After adrenalectomy, severe hypotension resulting in circulatory collapse and shock may occur.

Assessment findings

The cardinal sign of pheochromocytoma is persistent or paroxysmal hypertension. The patient's history may reveal unpredictable episodes of hypertensive crisis, paroxysmal symptoms suggestive of a seizure disorder or anxiety attacks, hypertension that responds poorly to conventional treatment and, in some cases, hypotension or shock, resulting from surgery or diagnostic procedures.

The patient may describe attacks of such signs and symptoms as headache, palpitations, visual blurring, nausea, vomiting, severe diaphoresis, feelings of impending doom, and precordial or abdominal pain. Any activity or condition that displaces the abdominal contents, such as heavy lifting, exercises, bladder distention, or pregnancy may precipitate the attacks. Severe attacks may be precipitated by the administration of opiates, histamine, glucagon, and corticotropin. Sometimes, no precipitating event is found.

The patient may also report mild to moderate weight loss caused by increased metabolism. In addition, he may have symptoms related to orthostatic hypotension: dizziness, light-headedness, or faintness when rising to an upright position.

Inspection may reveal tachypnea, pallor, or flushing accompanied by profuse sweating during an attack. Tremor and seizures may also occur.

During an attack, palpation may reveal moist, cool hands and feet or generalized warmth and flushing. Tachycardia is usually present. The tumor itself is rarely palpable, but when it is, palpation of the surrounding area may induce a typical acute attack and help to confirm the diagnosis.

Auscultation of blood pressure reveals hypertension, the most common manifestation. Although hypertension is sustained in most patients, some lability is usually

noted. During an attack, blood pressure may increase to dangerously high levels.

Diagnostic tests

Diagnosis of pheochromocytoma is usually based on the following test findings:

- u Increased urinary excretion of total free catecholamine and its metabolites, vanillylmandelic acid (VMA) and metanephrine, as measured by analysis of a 24-hour urine specimen, confirms pheochromocytoma.
- u Labile blood pressure necessitates urine collection during a hypertensive episode and comparison of this specimen to a baseline specimen. Direct assay of total plasma catecholamines may show levels 10 to 50 times higher than normal.
- u Computed tomography (CT) scanning or magnetic resonance imaging of the adrenal glands is usually successful in identifying the intra-adrenal lesions. CT scanning, chest X-rays, or abdominal aortography may be used to identify extra-adrenal pheochromocytomas.

Treatment

Surgical removal of the tumor is the treatment of choice. To decrease the patient's blood pressure, the alpha-adrenergic blocking agents phentolamine or phenoxybenzamine, or metyrosine (which blocks catecholamine synthesis), are administered from 1 day to 2 weeks before surgery or invasive diagnostic procedures. A beta-adrenergic blocking agent (propranolol or atenolol) may also be used after achieving alpha blockade. Prazosin, labetalol, and nifedipine may also be used.

Postoperatively, the patient may require I.V. fluids, plasma volume expanders and, possibly, transfusions if marked hypotension occurs. However, persistent hypertension in the immediate postoperative period is more common.

If surgery isn't feasible, alpha- and beta-adrenergic blocking agents—such as phenoxybenzamine and propranolol, respectively—are beneficial in controlling catecholamine effects and preventing attacks. Research is being done to investigate the use of a combination of chemotherapeutic agents in treating inoperable malignant adrenal tumors.

Management of acute attacks or hypertensive crisis requires administration of phentolamine by I.V. push or drip or nitroprusside to normalize blood pressure.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered tissue perfusion (cardiopulmonary, renal)
- u Anxiety
- u Fear
- u Ineffective individual coping
- u Knowledge deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient's vital signs will remain normal.
- u The patient's intake will equal her output.
- u The patient's cardiac output will remain normal.
- u The patient will express feelings of comfort.
- u The patient will avoid complications.

Nursing interventions

- u To ensure the reliability of urine catecholamine measurements, keep the patient at rest and make sure he avoids foods high in vanillin (such as coffee, nuts, chocolate, and bananas) for 2 days before urine collection of VMA. Also, be aware that some drugs—such as guaifenesin and salicylates—may interfere with the accurate determination of VMA. When possible, avoid administering these medications before the test. Collect the urine in a special receptacle containing hydrochloric acid that has been prepared by the laboratory. Don't schedule the test if the patient was recently exposed to iodine-containing radiographic contrast media because they can suppress the levels of urine catecholamine.
- u Monitor the patient's blood pressure because transient hypertensive attacks are possible. Tell him to report headaches, palpitations, nervousness, or other symptoms of an acute attack.
- u If hypertensive crisis develops, monitor blood pressure and heart rate every 2 to 5 minutes until blood pressure stabilizes at an acceptable level.
- u Administer analgesics for headache. Provide comfort measures: Decrease environmental stimuli, apply ice packs, and avoid abrupt jarring motions.
- u Monitor serum glucose levels and observe for weight loss from hypermetabolism.
- u Monitor peripheral circulation, neurologic status, and renal and cardiac function for signs of adequate perfusion.
- u Help the patient decrease anxiety by encouraging him to verbalize feelings and fears, listening actively, and answering questions. Help the patient identify and use his strengths to develop coping strategies.
- u Consult a dietitian to plan a high-protein diet that has adequate calories.

After adrenalectomy:

- u The first 24 to 48 hours after surgery are the most critical. Monitor vital signs; blood pressure may increase or decrease sharply.

ALERT Keep the patient quiet because excitement can trigger a hypertensive episode. Postoperative hypertension is common because the stress of surgery and manipulation of the adrenal gland stimulate secretion of catecholamines. This excess secretion causes profuse sweating, so keep the room cool and change the patient's clothing and bedding often.

- u If the patient receives phentolamine, monitor his blood pressure closely. Observe and record adverse drug reactions, such as dizziness, weakness, hypotension, tachycardia, and diarrhea.
- u Watch for abdominal distention and return of bowel sounds.
- u Check dressings and vital signs for indications of hemorrhage (increased pulse rate, decreased blood pressure, cold and clammy skin, pallor, and unresponsiveness).
- u Give analgesics for pain, as ordered, but monitor blood pressure carefully. Many analgesics, especially meperidine, can cause hypotension.
- u If autosomal dominant transmission of pheochromocytoma is suspected, suggest that family members be genetically evaluated for this condition.

Patient teaching

- u Provide honest and clear explanations of all procedures to allay the patient's fears.
- u Teach the patient methods that help prevent paroxysmal attacks; for example, relaxation techniques to reduce anxiety, adequate fluids and fiber to avoid constipation, and adequate rest to avoid fatigue.
- u Teach the patient and family members to report signs of adrenal insufficiency and adverse effects of replacement therapy. Warn against abrupt discontinuation of medication. Advise the patient that lifelong treatment is necessary.
- u Encourage the patient to wear a medical identification bracelet and to carry her medication with her at all times.

Pancreatic and other disorders

Endocrine imbalances can cause insulin deficiency, gonadal abnormalities, precocious puberty, and male infertility.

DIABETES MELLITUS

Diabetes mellitus is a chronic disease of absolute or relative insulin deficiency or resistance. It's characterized by disturbances in carbohydrate, protein, and fat metabolism. Insulin transports glucose into the cells for use as energy and storage as glycogen. It also stimulates protein synthesis and free fatty acid storage in the adipose tissues. Insulin deficiency compromises the body tissues' access to essential nutrients for fuel and storage.

Diabetes mellitus occurs in two primary forms: type I, characterized by absolute insufficiency, and the more prevalent type II, characterized by insulin resistance with varying degrees of insulin secretory defects.

Onset of type I usually occurs before age 30, although it may occur at any age; the patient usually is thin and requires exogenous insulin and dietary management to achieve control. type II usually occurs in obese adults after age 40, although it's commonly seen in North American youths. It's often treated with diet and exercise, in combination with antidiabetic drugs; treatment may include insulin therapy.

Diabetes mellitus is thought to affect about 8% of the population of the United States (16 million people); about half are undiagnosed. Incidence is higher in males than in females and increases with age.

Causes and pathophysiology

The effects of diabetes mellitus result from insulin deficiency. Insulin transports glucose into the cell for use as energy and storage as glycogen. It also stimulates protein synthesis and free fatty acid storage. Insulin deficiency compromises the body tissues' access to essential nutrients for fuel and storage.

The etiology of both type I and type II diabetes remains unknown. Genetic factors may play a part in the development of all types. Autoimmune disease and viral infections may be risk factors in type I.

Other risk factors include:

- u obesity, which contributes to the resistance to endogenous insulin
- u physiologic or emotional stress, which can cause prolonged elevation of stress hormone levels (cortisol, epinephrine, glucagon, and growth hormone); this increases blood glucose levels, which, in turn, places increased demands on the pancreas
- u pregnancy, which causes weight gain and increases levels of estrogen and placental hormones, which antagonize insulin
- u some medications that can antagonize the effects of insulin, including thiazide diuretics, adrenal corticosteroids, and oral contraceptives.

Complications

Two acute metabolic complications of diabetes are ketoacidosis and hyperosmolar coma (hyperosmolar nonketotic diabetic coma). These life-threatening conditions require immediate medical intervention. (See [*Understanding ketoacidosis and hyperosmolar coma.*](#))

Patients with diabetes mellitus also have a higher risk for various chronic illnesses affecting virtually all body systems. The most common chronic complications include cardiovascular disease, peripheral vascular disease, retinopathy, nephropathy, diabetic dermopathy, and peripheral and autonomic neuropathy. Nearly two-thirds of persons with diabetes die because of cardiovascular disease. It's also the leading cause of renal failure and blindness.

Peripheral neuropathy usually affects the hands and feet and may cause numbness or pain. Autonomic neuropathy manifests itself in several ways, including gastroparesis (leading to delayed gastric emptying and a feeling of nausea and fullness after meals), nocturnal diarrhea, impotence, and postural hypotension.

Hyperglycemia impairs the patient's resistance to infection because the glucose content of the epidermis and urine encourages bacterial growth. The patient is susceptible to skin and urinary tract infections and vaginitis.

Infants of diabetic mothers have a two- to three-times-greater incidence of congenital malformations and fetal distress. Patients with diabetes mellitus also have an increased incidence of cognitive depression.

Assessment findings

The patient with type I diabetes usually reports rapidly developing symptoms. With type II diabetes, the patient's symptoms are usually vague, long-standing, and develop gradually. Insulin deficiency causes hyperglycemia, which pulls fluid from body tissues, causing osmotic diuresis, polyuria, dehydration, polydipsia, dry mucous membranes, and poor skin turgor. Patients with type II diabetes generally report a family history of diabetes mellitus, gestational diabetes or the delivery of a baby weighing more than 9 lb (4 kg), severe viral infection, other endocrine disease, recent stress or trauma, or use of drugs that increase blood glucose levels.

In ketoacidosis and hyperosmolar nonketotic state, dehydration can cause hypovolemia and shock. Wasting of glucose in the urine usually produces weight loss and hunger in uncontrolled type I diabetes, even if the patient eats voraciously. Patients may complain of weakness; vision changes; frequent skin and urinary tract infections; dry, itchy skin; sexual problems; and vaginal discomfort, all of which are symptoms of hyperglycemia.

Inspection may show retinopathy or cataract formation. Skin changes, especially on the legs and feet, may represent impaired peripheral circulation. Muscle wasting and loss of subcutaneous fat may be evident in type I diabetes; type II is characterized by obesity, particularly in the abdominal area. Long-term effects produce signs of neuropathy, atherosclerosis, and peripheral and autonomic neuropathy. Peripheral neuropathy usually affects hands and feet and may produce numbness or pain. A patient with autonomic neuropathy may present with gastroparesis leading to delayed gastric emptying and a feeling of nausea or fullness after eating. Nocturnal diarrhea and impotence can also occur.

Palpation may disclose poor skin turgor and dry mucous membranes related to dehydration. Decreased peripheral pulses, cool skin temperature, and decreased reflexes may also be palpable. Auscultation may reveal orthostatic hypotension. Patients with ketoacidosis may have a characteristic “fruity” breath odor because of increased acetone production.

Diagnostic tests

In nonpregnant adults, diabetes mellitus is diagnosed when they present with:

- u at least two occasions of fasting plasma glucose level greater than or equal to 126 mg/dl
- u typical symptoms of uncontrolled diabetes and a random blood glucose level greater than or equal to 200 mg/dl
- u blood glucose level greater than or equal to 200 mg/dl 2 hours after ingestion of 75 g of oral dextrose.

Two of the above tests are required for diagnosis; they can be the same two tests or any combination and may be separated by more than 24 hours.

An ophthalmologic examination may show diabetic retinopathy.

Other diagnostic and monitoring tests include urinalysis for acetone and blood testing for glycosylated hemoglobin, which reflects glucose control over the past 2 to 3 months.

Treatment

For patients with type I diabetes, treatment includes insulin replacement, diet, and exercise. Current forms of insulin-replacement include single-dose, mixed-dose,

split-mixed dose, and multiple-dose regimens. The multiple-dose regimens may include use of an insulin pump.

Human insulin may be rapid-acting (Regular), intermediate-acting (NPH or Lente), long-acting (Ultralente), or a combination of rapid-acting and intermediate-acting (70/30 or 50/50 of NPH and Regular) mixed together.

Insulin Lispro may be used in place of Regular insulin. It's rapid in onset (15 minutes) and waiting to eat after injection isn't necessary. It has a short duration of action (4 hours), which decreases between-meal and nocturnal hypoglycemia.

Pancreas transplantation is available and requires chronic immunosuppression.

Patients with type 2 diabetes may require oral antidiabetic drugs to stimulate endogenous insulin production, increase insulin sensitivity at the cellular level, suppress hepatic gluconeogenesis, and delay GI absorption of carbohydrates.

A patient with either type of diabetes requires a diet that is planned to meet nutritional needs, control blood glucose levels, and reach and maintain appropriate body weight.

For the obese patient with type II diabetes, the calorie allotment may be high, depending on growth stage and activity level. For success, the diet must be followed consistently, with meals eaten at regular times.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Altered nutrition: More than body requirements u Altered tissue perfusion (renal, cardiovascular, peripheral) u Altered urinary elimination u Fluid volume deficit u Impaired skin integrity u Ineffective family coping: Disabling u Ineffective individual coping u Knowledge deficit u Risk for infection u Risk for injury u Sensory or perceptual alterations (visual) u Sexual dysfunction

PATHOPHYSIOLOGY

Understanding ketoacidosis and hyperosmolar coma

Ketoacidosis and hyperosmolar coma are acute complications of hyperglycemic crisis that may occur in the diabetic patient. If not treated properly, either may result in coma or death.

Ketoacidosis occurs most often in patients with type I diabetes; in fact, it may be the first evidence of previously unrecognized type I diabetes. Hyperosmolar coma occurs most often in patients with type II diabetes. But hyperosmolar coma may also occur in anyone whose insulin tolerance is stressed and in patients who have undergone certain therapeutic procedures —such as peritoneal dialysis, hemodialysis, tube feedings, or total parenteral nutrition.

Acute insulin deficiency (absolute in ketoacidosis; relative in hyperosmolar coma) precipitates both conditions. Causes include illness, stress, infection, and failure to take insulin (only in a patient with ketoacidosis).

Buildup of glucose

Inadequate insulin hinders glucose uptake by fat and muscle cells. Because the cells can't take in glucose to convert to energy, glucose accumulates in the blood. At the same time, the liver responds to the demands of the energy-starved cells by converting glycogen to glucose and releasing glucose into the blood, *further* increasing the blood glucose level. When this level exceeds the renal threshold, excess glucose is excreted in the urine.

Still, the insulin-deprived cells can't utilize glucose. Their response is rapid metabolism of protein, which results in loss of intracellular potassium and phosphorus and in excessive liberation of amino acids. The liver converts these amino acids into urea and glucose.

As a result of these processes, blood glucose levels are grossly elevated. The aftermath is increased serum osmolarity and glucosuria (higher in hyperosmolar coma than in ketoacidosis because blood glucose levels are higher in hyperosmolar coma), leading to osmotic diuresis.

A deadly cycle

The massive fluid loss from osmotic diuresis causes fluid and electrolyte imbalances and dehydration. Water loss exceeds electrolyte loss, contributing to hyperosmolarity. This, in turn, perpetuates dehydration, decreasing the glomerular filtration rate and reducing the amount of glucose excreted in the urine. This leads to a deadly cycle: Diminished glucose excretion *further* raises blood glucose levels, producing severe hyperosmolarity and dehydration and finally causing shock, coma, and death.

Further ketoacidosis complication

All these steps hold true for both ketoacidosis and hyperosmolar coma. But ketoacidosis has an additional simultaneous process that leads to metabolic acidosis. The absolute insulin deficiency causes cells to convert fats into glycerol and fatty acids for energy. The fatty acids can't be metabolized as quickly as they're released, so they accumulate in the liver, where they're converted into ketones (ketoacids). These ketones accumulate in the blood and urine and cause acidosis. Acidosis leads to more tissue breakdown, more ketosis, more acidosis, and eventually shock, coma, and death.

Key outcomes

- u The patient will maintain current body weight.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will maintain adequate peripheral pulses.
- u The patient's intake will equal his output.
- u The patient won't develop complications.
- u The patient and family members will verbalize understanding of the condition and treatment modality.
- u The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behaviors.

Nursing interventions

- u Keep accurate records of vital signs, weight, fluid intake, urine output, and calorie intake. Monitor serum glucose and urine acetone levels.

- u Monitor for acute complications of diabetic therapy, especially hypoglycemia (vagueness, slow cerebration, dizziness, weakness, pallor, tachycardia, diaphoresis, seizures, and coma); immediately give carbohydrates in the form of fruit juice, hard candy, honey or, if the patient is unconscious, glucagon or I.V. dextrose. Also be alert for signs of hyperosmolar coma (polyuria, thirst, neurologic abnormalities, and stupor). This hyperglycemic crisis requires I.V. fluids and insulin replacement.
- u Monitor diabetic effects on the cardiovascular system, such as cerebrovascular, coronary artery, and peripheral vascular impairment, and on the peripheral and autonomic nervous systems.
- u Provide meticulous skin care, especially to the feet and legs. Treat all injuries, cuts, and blisters. Avoid constricting hose, slippers, or bed linens. Refer the patient to a podiatrist.
- u Observe for signs of urinary tract and vaginal infections. Encourage adequate fluid intake.
- u Monitor the patient for signs of diabetic neuropathy (numbness or pain in the hands and feet, footdrop, and neurogenic bladder).
- u Consult a dietitian to plan a diet with the recommended allowances of calories, protein, carbohydrates, and fats, based on the patient's particular requirements.
- u Encourage the patient to verbalize feelings about diabetes and its effects on lifestyle and life expectancy. Offer emotional support and a realistic assessment of his condition. Stress that with proper treatment, he can have a near-normal lifestyle and life expectancy. Assist the patient to develop coping strategies. Refer him and family members to a counselor, if necessary. Encourage them to join a support group.

Patient teaching

- u Stress the importance of carefully adhering to the prescribed program and blood glucose control. Tailor your teaching to the patient's needs, abilities, and developmental stage. Discuss diet, medications, exercise, monitoring techniques, hygiene, and how to prevent and recognize hypoglycemia and hyperglycemia.
- u To encourage compliance to lifestyle changes, emphasize how blood glucose control affects long-term health. Teach the patient how to care for his feet: He should wash them daily, carefully dry between his toes, and inspect for corns, calluses, redness, swelling, bruises, and breaks in the skin. Urge him to report any skin changes to the doctor. Advise him to wear comfortable, nonconstricting shoes and never to walk barefoot.
- u Urge annual regular ophthalmologic examinations for early detection of diabetic retinopathy.
- u Describe the signs and symptoms of diabetic neuropathy and emphasize the need for safety precautions because decreased sensation can mask injuries.
- u Teach the patient how to manage diabetes when he has a minor illness, such as a cold, flu, or upset stomach.
- u To prevent diabetes, teach people at high risk to avoid risk factors; for example, maintaining proper weight and exercising regularly. Advise genetic counseling for adult diabetic patients who are planning families.
- u Teach the patient and family members how to monitor the patient's diet. Teach how to read labels in the supermarket to identify fat, carbohydrate, protein, and sugar content.
- u Encourage the patient and family to contact the Juvenile Diabetes Foundation, the American Association of Diabetes Educators, and the American Diabetes Association to obtain additional information.

HYPOGONADISM

Hypogonadism—resulting from decreased androgen production in males—usually causes infertility and inhibits the development of normal secondary sex characteristics. Primary and secondary forms exist, and the disorder is classified by the age of onset (prepuberty or postpuberty) or the location of the causative lesion. In primary (hypergonadotropic) hypogonadism, the lesion is in the testes; in secondary (hypogonadotropic) hypogonadism, the lesion is in the hypothalamic-pituitary area.

Causes and pathophysiology

Primary hypogonadism results directly from interstitial (Leydig's cell) cellular or seminiferous tubular damage due to faulty development or mechanical damage. This causes increased secretion of gonadotropins (follicle-stimulating hormone [FSH] and luteinizing hormone [LH]) by the pituitary gland in an attempt to increase the testicular functional state. It includes the following disorders: Klinefelter's syndrome, Reifenstein's syndrome, male Turner's syndrome, Sertoli-cell—only syndrome, anorchism, orchitis, and sequelae of irradiation.

Secondary hypogonadism results from faulty interaction within the hypothalamic-pituitary axis, resulting in failure to secrete normal levels of gonadotropins. It includes the following disorders: hypopituitarism, isolated FSH deficiency, isolated LH deficiency, prolactinomas, Kallmann's syndrome, and Prader-Willi syndrome.

Complications

Hypogonadism may lead to such complications as infertility, eunuchism (total gonadal failure), eunuchoidism (partial gonadal failure), low-grade chronic anemia, diabetes mellitus, vasomotor instability, osteoporosis, skeletal malformations due to incomplete epiphyseal closure, malignancies, and autoimmune disorders.

Assessment findings

Clinical effects of hypogonadism vary with the specific cause and the age of onset. Adults may report diminished sex drive and potency and regression of secondary sex characteristics. Young patients may have a history of delayed puberty.

Patients may have an infantile penis and small, soft, or absent testes; gynecomastia; below-average muscle development and strength; increased length of the long bones; fine, sparse facial hair; scant or absent axillary, pubic, and body hair; girdle obesity; small Adam's apple; lack of temporal recession of the hairline; kyphosis; and a high-pitched voice.

Diagnostic tests

Serum gonadotropin levels increase in primary hypogonadism but decrease in secondary hypogonadism.

Serum testosterone levels are low.

Other hormonal studies are used to assess neuroendocrine functions, such as thyrotropin, adrenocorticotropin, growth hormone, prolactin, and vasopressin levels.

Chromosomal analysis may be used to detect the specific cause.

Testicular biopsy and semen analysis are used to determine sperm production and identify impaired spermatogenesis.

X-rays and bone scans may show delayed closure of the epiphyses and immature bone age.

Treatment

In primary hypogonadism, treatment may consist of hormone replacement, especially with testosterone, FSH, methyltestosterone, or human chorionic gonadotropin (HCG). Treatment for secondary hypogonadism is HCG alone. Fertility can't be restored after permanent testicular damage, but eunuchism resulting from hypothalamic-pituitary lesions can be corrected with gonadotropins to stimulate testicular function.

Nursing diagnoses

- u Altered growth and development
- u Body image disturbance
- u Ineffective individual coping
- u Knowledge deficit
- u Low self-esteem
- u Sexual dysfunction

Key outcomes

- u The patient will demonstrate age-appropriate behavior to the extent possible.

- u The patient will express positive feelings about self.
- u The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behaviors.
- u The patient will voice feelings related to self-esteem.
- u The patient will avoid complications.

Nursing interventions

- u Encourage the patient to verbalize his feelings about his condition. Help him to develop coping strategies.
- u Refer the patient to a mental health professional or for sexual counseling, if appropriate.

Patient teaching

- u Teach the patient and family members about normal growth and development and how the patient may differ.
- u Review long-term hormone therapy. Explain how to identify and report adverse effects, such as acne and water retention. Urge the patient to take the drugs exactly as directed and not to stop taking the drugs abruptly.
- u Encourage family members to obtain genetic counseling.

PRECOCIOUS PUBERTY IN FEMALES

In girls, precocious puberty involves early pubertal changes: breast development, pubic and axillary hair growth, and menarche before age 8. In true precocious puberty, the ovaries mature and pubertal changes progress in an orderly manner. In pseudoprecocious puberty, pubertal changes occur without ovarian maturation.

Causes

About 85% of all cases of true precocious puberty in females are constitutional, resulting from early development and activation of the endocrine glands without corresponding abnormalities. Other causes of true precocious puberty include central nervous system (CNS) disorders, such as hypothalamic tumors, intracranial tumors (pinealoma, granuloma, and hamartoma), hydrocephaly, degenerative encephalopathy, tuberous sclerosis, neurofibromatosis, encephalitis, skull injuries, and meningitis.

Pseudoprecocious puberty may result from increased levels of sex hormones due to ovarian and adrenocortical tumors, adrenocortical virilizing hyperplasia, ingestion of estrogens or androgens, and increased end-organ sensitivity to low levels of circulating sex hormones.

Complications

Early signs of sexual development can cause emotional problems. If ovulation is occurring, pregnancy is possible. Short stature may result from premature epiphyseal closure. As an adult, the patient experiences excessive menstrual bleeding, causing anemia. Cystic mastitis and an increased incidence of uterine adenofibromas are also linked with this disorder. Compression of surrounding tissues by intracranial tumors may result in hemorrhage, necrosis, and increased intracranial pressure. Malignant estrogen-secreting tumors may be fatal.

Assessment findings

The patient's history shows a rapid growth spurt before age 9. Inspection may reveal thelarche (breast development), pubarche (pubic hair development), and menarche—all before age 8. These changes may occur independently or simultaneously.

Diagnostic tests

X-ray studies of hands, wrists, knees, and hips show bone age and premature epiphyseal closure.

Blood analyses of serum gonadotropin (follicle-stimulating hormone [FSH] and luteinizing hormone [LH]) and sex steroid (estradiol and progesterone) levels are in the normal adult range. Low levels of gonadotropins indicate an ovarian or adrenal tumor; high levels suggest an intracranial lesion or a human chorionic gonadotropin-secreting tumor.

Laboratory tests, including vaginal smear and estrogen secretion, urinalysis for gonadotropic activity and excretion of 17-ketosteroids, and radioimmunoassay for both FSH and LH, define elevated values.

Ultrasonography, computed tomography (CT) scans, magnetic resonance imaging (MRI), laparoscopy, or exploratory laparotomy results may verify an abdominal lesion.

EEG, ventriculography, pneumoencephalography, CT scans, MRI, or angiography can be used to detect CNS disorders.

Treatment

Although still controversial, treatment of constitutional true precocious puberty may include medroxyprogesterone to reduce secretion of gonadotropins and prevent menstruation. Adrenogenital syndrome requires cortical or adrenocortical steroid replacement. Surgery may be needed to remove ovarian and adrenal tumors. Regression of secondary sex characteristics may follow such surgery, especially in young children. Choriocarcinomas may necessitate surgery, irradiation, or chemotherapy. Treatment for hypothyroidism requires thyroid extract or levothyroxine to decrease gonadotropic secretions.

Nursing diagnoses

- u Altered growth and development
- u Body image disturbance
- u Impaired adjustment
- u Ineffective individual coping
- u Knowledge deficit

Key outcomes

- u The patient will demonstrate age-appropriate skills and behavior to the extent possible.
- u The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behaviors.
- u The patient will express positive feelings about self.
- u The patient will voice feelings related to self-esteem.

Nursing interventions

- u Encourage the child and parents to verbalize their feelings about changes in the child's body image.
- u Explain all diagnostic procedures and offer honest and realistic information about the child's condition.
- u Help the child to develop coping strategies.
- u Refer family members to a mental health professional for additional counseling, if necessary.
- u Advise parents to dress the child in age-appropriate clothing that de-emphasizes her physical development.
- u Reassure the parents that precocious puberty usually doesn't precipitate precocious sexual behavior.
- u If the patient requires surgery to remove a tumor, take appropriate preoperative and postoperative measures.

Patient teaching

- u Teach the parents and child about normal development and how the child may differ. Explain that although the patient appears physically mature, she isn't psychologically mature. Warn them that the discrepancy between physical and psychological maturity may create problems. Caution them against expecting more of her than of other children her age.
- u Provide appropriate sex education. Include information on menstruation and related hygiene.
- u Teach the parents and child to identify and report adverse effects of medications. Stress the importance of complying with long-term treatment.

PRECOCIOUS PUBERTY IN MALES

Boys who begin to mature sexually before age 10 exhibit one of two forms of precocious puberty, also called isosexual precocity. The most common form is true precocious puberty, characterized by early maturation of the hypothalamic-pituitary-gonadal axis, development of secondary sex characteristics, gonadal development, and spermatogenesis. Pseudoprecocious puberty induces development of secondary sex characteristics without gonadal development. Boys with true precocious puberty reportedly have fathered children as early as age 7.

In most boys with precocious puberty, sexual characteristics develop in essentially normal sequence. These children function normally when they reach adulthood.

Causes

True precocious puberty may be idiopathic (constitutional) or cerebral (neurogenic). In some patients, idiopathic precocity may be genetically transmitted as a dominant trait. Cerebral precocity results from pituitary or hypothalamic intracranial lesions that cause excessive secretion of gonadotropin.

Pseudoprecocious puberty may result from testicular tumors (hyperplasia, adenoma, or carcinoma) or from congenital adrenogenital syndrome. Testicular tumors create excessive testosterone levels; adrenogenital syndrome creates high levels of adrenocortical steroids. Deficiencies of 11 β -hydroxylase or 21-hydroxylase may also cause precocious puberty in males.

Complications

Emotional disturbances may result from premature sexual development. Premature closure of the epiphyses results in stunted adult stature. Tumors of the pituitary gland may cause compression and necrosis of surrounding tissue. Increased intracranial pressure, vision disturbances, and seizure disorders may also occur. Malignant tumors are usually fatal.

Assessment findings

The patient's history may disclose altered growth patterns, behavior changes, family history of precocious puberty, or ingestion of hormones. Parents may note that the child had an initial growth spurt and early muscle development. The patient with precocity due to cerebral lesions may report nausea, vomiting, headache, and vision disturbances.

In all patients, inspection may reveal an adult hair pattern, penile growth, and bilateral enlarged testes. In pseudoprecocity caused by a testicular tumor, you may also observe acne and a discrepancy in testis size. Adrenogenital syndrome produces adult skin tone, excessive hair (including beard), and a deepened voice. A boy with this syndrome appears stocky and muscular; his penis and scrotal sac are enlarged.

In true precocious puberty, palpation may reveal bilaterally enlarged testes at an early age. The patient with pseudoprecocity due to testicular tumors has an enlarged testis that may be hard or contain a palpable, isolated nodule. If adrenogenital syndrome is the cause, the scrotal sac and prostate are enlarged, but not the testes.

Diagnostic tests

In true precocious puberty:

- u Serum luteinizing hormone, follicle-stimulating hormone, and corticotropin levels are elevated.
- u Plasma testosterone levels increase to adult levels.
- u Ejaculate evaluation may reveal live spermatozoa.
- u Brain scan, magnetic resonance imaging, skull X-rays, and EEG may be used to detect central nervous system tumors.
- u Skull and hand X-rays show advanced bone age.

In pseudoprecocious puberty:

- u Chromosomal karyotype analysis may demonstrate an abnormal pattern of autosomes and sex chromosomes.
- u Adrenal androgen levels are elevated.

Treatment

Boys with idiopathic precocious puberty generally require no medical treatment and, except for stunted growth, experience no physical complications in adulthood. Psychological counseling is important. Medroxyprogesterone may be used to inhibit gonadotropin secretion.

When precocious puberty is caused by tumors, the prognosis is discouraging. Brain tumors require neurosurgery but commonly resist treatment and may be fatal. Radiation therapy is used when indicated. A hypothalamic hamartoma requires a gonadotropin-releasing hormone (Gn-RH) analogue; idiopathic neurogenic precocious puberty demands a long-acting Gn-RH analogue. A patient with testicular tumor may be treated by removing the affected testis (orchiectomy). Malignant tumors also necessitate chemotherapy and lymphatic radiation therapy.

When precocious puberty results from an autosomal dominant disorder, the goal of treatment is to block androgen and estrogen stimulation. Spironolactone and testolactone are sometimes used. The antifungal agent ketoconazole is being tested for its inhibitory effect on the biosynthesis of adrenal and gonadal steroids.

Adrenogenital syndrome that causes precocious puberty may respond to lifelong therapy with glucocorticoids (cortisol) to inhibit corticotropin production.

Nursing diagnoses

- u Altered growth and development
- u Body image disturbance
- u Impaired adjustment
- u Ineffective individual coping
- u Knowledge deficit

Key outcomes

- u The patient will demonstrate age-appropriate skills and behavior to the extent possible.
- u The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behaviors.
- u The patient will express positive feelings about self.
- u The patient will voice feelings related to self-esteem.

Nursing interventions

- u Encourage the child to verbalize his feelings about changes in his body. Offer emotional support and help the child develop coping strategies. Refer the patient and family members to a counselor, if necessary.
- u If the patient has a tumor, provide appropriate preoperative and postoperative care and emotional support.

Patient teaching

- u Teach the child and family members about normal growth and development and how the patient may differ. Emphasize that the child's social and emotional development should remain consistent with his chronological age, not with his physical development.
- u Stress the importance of continuing medical follow-up care and testing.
- u Teach the patient and family members to identify and report adverse effects (cushingoid symptoms) of androgen antagonistic medication.
- u If the child is being treated with the luteinizing hormone-releasing hormone (LH-RH) analogue histrelin, instruct the parents to administer the drug in the evening to counteract the nocturnal surge of endogenous LH-RH. Teach the parents and child how to administer the drug by subcutaneous injection and to identify and report skin reactions at the injection site.
- u Advise the child to wear medical identification.

MALE INFERTILITY

When a couple fails to achieve pregnancy after about 1 year of regular, unprotected intercourse, male infertility may be the reason. About half of the infertility problems in the United States are attributed to the male.

Causes

Some of the factors that cause male infertility include:

- u varicocele
- u a mass of dilated and tortuous varicose veins in the spermatic cord
- u semen disorders, such as volume or motility disturbances or inadequate sperm density
- u proliferation of abnormal or immature sperm with variations in the size and shape of the head
- u systemic disease, such as diabetes mellitus, neoplasms, hepatic and renal diseases, and viral disturbances, especially mumps orchitis
- u genital infections, such as gonorrhea and herpes
- u disorders of the testes, such as cryptorchidism, Sertoli-cell—only syndrome, and ductal obstruction (caused by absence or ligation of vas deferens or infection)
- u genetic defects, such as Klinefelter's syndrome (chromosomal pattern XXY, eunuchoidal habitus, gynecomastia, and small testes) or Reifenstein's syndrome (chromosomal pattern 46,XY, reduced testosterone, azoospermia, eunuchoidism, and hypospadias)
- u immune disorders, such as autoimmune infertility
- u endocrine imbalance that disrupts pituitary gonadotropins, inhibiting spermatogenesis, testosterone production, or both (occurring in Kallmann's syndrome, panhypopituitarism, hypothyroidism, and congenital adrenal hyperplasia)
- u chemicals and drugs that can inhibit gonadotropins or interfere with spermatogenesis, such as arsenic, methotrexate, medroxyprogesterone, nitrofurantoin, monoamine oxidase inhibitors, and some antihypertensives
- u sexual problems, such as erectile dysfunction, ejaculatory incompetence, or low libido
- u other factors, such as age, trauma to the testes, and alcohol or marijuana use.

Complications

Male infertility often causes anger, hurt, disgust, guilt, and loss of self-esteem—in both partners. Psychological distress may also be linked with male infertility.

Assessment findings

Patient history may reveal abnormal sexual development, delayed puberty, previous infertility, and a history of prolonged fever, mumps, impaired nutritional status, genital surgery or trauma, or alcohol or marijuana use. Inspection may reveal atrophied testes, empty scrotum, scrotal edema, varicocele, and penile nodes, warts, plaques, or hypospadias. The seminal vesicles may feel warm. You may feel beading or abnormal nodes on the spermatic cord and vas deferens, anteversion of the epididymis, and prostatic enlargement, nodules, swelling, or tenderness.

Diagnostic tests

The most conclusive test for male infertility is semen analysis. Other tests include gonadotropin assay to determine the integrity of the pituitary gonadal axis; serum testosterone evaluation to determine end-organ response to luteinizing hormone (LH); urine 17-ketosteroid levels to measure testicular function; and testicular biopsy to clarify unexplained oligospermia and azoospermia. Vasography and seminal vesiculography may also help.

Treatment

Infertility resulting from anatomic dysfunction or infection requires correction of the underlying problem. A varicocele requires surgical repair or removal. Patients with sexual dysfunction need education, counseling, or special therapy. Decreased follicle-stimulating hormone may respond to vitamin B therapy. Decreased LH levels may respond to chorionic gonadotropin. Normal or elevated LH requires low dosages of testosterone. Low testosterone levels, decreased semen motility, and volume disturbances may respond to chorionic gonadotropin.

Patients with oligospermia who have a normal history and physical examination, normal hormonal assays, and no signs of systemic disease require emotional support and counseling, adequate nutrition, multivitamins, and selective therapeutic agents, such as clomiphene, chorionic gonadotropin, and low doses of testosterone. Alternatives to such treatment are adoption and artificial insemination.

Nursing diagnoses

- u Body image disturbance
- u Ineffective family coping
- u Ineffective individual coping
- u Knowledge deficit
- u Self-esteem disturbance

Key outcomes

- u The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behaviors.
- u The patient will express positive feelings about self.
- u The patient will voice feelings related to self-esteem.
- u The patient will avoid complications.

Nursing interventions

- u Encourage the couple to express their feelings, and help them develop coping strategies.
- u Refer them to a mental health professional and a fertility specialist for additional counseling, if necessary

Patient teaching

- u Teach patients ways to help prevent male infertility. (See [Preventing male infertility.](#))

- u Educate the couple about reproductive and sexual functions and about factors that may interfere with fertility, such as lubricants and douches.

PREVENTION

Preventing male infertility

Help prevent male infertility by encouraging patients to:

- u have regular physical examinations
- u protect the testicles during athletic activities
- u receive early treatment for sexually transmitted diseases
- u ask about surgical correction of anatomic defects.

- u Urge men with oligospermia to avoid habits that may interfere with normal spermatogenesis by elevating scrotal temperature, such as wearing tight underwear, taking hot tub baths, or habitually riding a bicycle. Cool scrotal temperatures are essential for adequate spermatogenesis.
- u Advise couples to join groups to share feelings and concerns with others who have the same problem.

TURNER'S SYNDROME

Turner's syndrome is caused by a chromosomal abnormality. It's the most common disorder of gonadal dysgenesis in females. It occurs in about 1 per 3,000 births; 95% of fetuses with this syndrome are spontaneously aborted. The syndrome produces characteristic signs, which are irreversible.

Causes

Turner's syndrome occurs when an X chromosome (or part of the second X chromosome) is missing from either the ovum or sperm through nondisjunction or chromosome lag. Mixed aneuploidy may result from mitotic nondisjunction.

Complications

In Turner's syndrome, complications include diabetes mellitus, thyroid disease, osteoarthritis, osteoporosis, cardiomyopathy, renal dysfunction, precocious aging, and sterility.

Assessment findings

Turner's syndrome produces characteristic signs that are obvious on inspection. At birth, 50% of infants with this syndrome measure below the third percentile in length. Commonly, they have swollen hands and feet, a wide chest, and a low hairline that becomes more obvious as they grow. They may have severe webbing of the neck, and some have coarse, enlarged, prominent ears. Gonadal dysgenesis is seen at birth. Inspection may also reveal pigmented nevi, lymphedema, hypoplasia, or malformed nails.

As the child grows, short stature is the most common physical manifestation. The patient may exhibit average to slightly below-average intelligence. Developmental problems include right-left disorientation for extrapersonal space and defective figure drawing. The patient is typically immature and socially naive.

Auscultation of the infant's chest indicates cardiovascular malformations, such as coarctation of the aorta and ventricular septal defects.

Diagnostic tests

Turner's syndrome can be diagnosed by chromosome analysis. Differential diagnosis should rule out mixed gonadal dysgenesis, Noonan's syndrome, and other similar disorders.

Treatment

Cardiovascular malformations must be corrected surgically. Hormonal replacement should begin in childhood and include androgen, human growth hormone and, possibly, small doses of estrogen. Later, progesterone and estrogen can induce sexual maturation.

Nursing diagnoses

- u Altered growth and development
- u Body image disturbance
- u Ineffective family coping: Disabling
- u Ineffective individual coping
- u Knowledge deficit
- u Low self-esteem
- u Sexual dysfunction

Key outcomes

- u The patient won't develop complications.
- u The patient and family members will verbalize understanding of the condition and treatment modality.
- u The patient and family members will agree to seek help from peer support groups or professional counselors to increase adaptive coping behaviors.
- u The patient will demonstrate age-appropriate behavior and skills to the extent possible.
- u The patient will express positive feelings about self.

Nursing interventions

- u Encourage the patient and family members to verbalize their feelings about the patient's condition and to discuss fear of rejection by others. Offer emotional support and a realistic assessment of the patient's condition.
- u Assist the patient and family members to develop coping strategies. Refer them for sexual or genetic counseling as necessary.
- u Provide appropriate preoperative and postoperative care for the infant with cardiovascular malformations.

Patient teaching

- u Explain the surgical procedure and its expected outcomes to the parents of the infant with cardiovascular malformations. Help them participate in the child's care and make informed decisions about treatment options. Explain all procedures and provide ongoing information about the infant's condition.
- u Teach the parents about normal growth and development and how their child may differ. Clarify any misconceptions and explain the treatment. Suggest strategies to help the child achieve age-related skills.
- u Teach family members and, if appropriate, the patient about long-term hormone replacement therapy. Stress the importance of strictly complying with therapy.

INTRODUCTION

Today, nursing care of the obstetric or gynecologic patient reflects a growing interest in improving the quality of women's health. In addition to assessing, counseling, and referring your patients, you need to consider such relevant factors as the desire to have children, problems of sexual adjustment, and self-image.

Frequently, nursing care is complicated by multiple and concurrent problems. For example, a patient with endometriosis may also have trichomonal vaginitis, dysuria, and unsuspected infertility. You can readily understand why multiple problems like these occur if you're familiar with the anatomy of the female genitalia.

External structures

Female genitalia include the following external structures, collectively known as the vulva: mons pubis (or mons veneris), labia majora, labia minora, clitoris, and the vestibule. The size, shape, and color of these structures—as well as pubic hair distribution and skin texture and pigmentation—vary greatly among individuals. The external structures undergo distinct changes during the life cycle. (See [External and internal female genitalia.](#))

The *mons pubis* is the pad of fat over the symphysis pubis (pubic bone). It's usually covered by the pubic hair that grows over the vulva after puberty.

The *labia majora* are the two thick, longitudinal folds of fatty tissue that extend from the mons pubis to the posterior aspect of the perineum. The labia majora protect the perineum and contain large sebaceous glands that help maintain lubrication. These structures are virtually absent in the young child; their development characteristically signals the onset of puberty. The skin of the more prominent parts of the labia majora is pigmented and darkens after puberty.

The *labia minora* are the two thin, longitudinal folds of skin that border the vestibule. They're firmer than the labia majora and extend from the clitoris to the fourchette.

The *clitoris* is the small, protuberant organ located just beneath the arch of the mons pubis. The clitoris contains erectile tissue, venous cavernous spaces, and specialized sensory corpuscles that are stimulated during coitus.

The *vestibule* is the oval space bordered by the clitoris, labia minora, and fourchette. The *urethral meatus* is located in the anterior portion of the vestibule; the *vaginal meatus* is in the posterior area of the vestibule. The *hymen* is the elastic membrane that partially obstructs the vaginal meatus in virgins.

Several glands lubricate the vestibule. *Skene's glands* open on both sides of the urethral meatus; *Bartholin's glands* open on both sides of the vaginal meatus.

Other anatomic structures include the *fourchette* (the posterior junction of the labia majora and labia minora) and the *perineum* (which includes the underlying muscles and fascia of the external surface of the pelvic floor that extends from the fourchette to the anus).

Internal structures

The internal female genitalia includes the vagina, cervix, uterus, fallopian tubes (or oviducts), and ovaries.

The *vagina* occupies the space between the bladder and the rectum. This muscular, membranous tube measures about 3" (7.6 cm) long. The vagina connects the uterus and the vestibule of the external genitalia. It serves as a passageway for sperm to the fallopian tubes, for the discharge of menstrual fluid, and for childbirth.

The *cervix*, or uterine neck, protrudes at least ¼" (0.6 cm) into the proximal end of the vagina. This rounded, conical structure joins the uterus and the vagina at a 45- to 90-degree angle.

The *uterus* is the hollow, pear-shaped organ in which the conceptus grows during pregnancy. The part of the uterus above the junction of the fallopian tubes is called the *fundus*; the part below this junction is called the *corpus*. The junction of the corpus and cervix forms the *lower uterine segment*.

The thick uterine wall consists of mucosal, muscular, and serous layers. The inner mucosal lining—the *endometrium*—undergoes cyclic changes to facilitate and maintain pregnancy.

The smooth muscular middle layer—the *myometrium*—interlaces the uterine and ovarian arteries and veins that circulate blood through the uterus. During pregnancy, this vascular system expands dramatically. Afterward, the myometrium contracts to constrict the vasculature and control the loss of blood.

The outer serous layer, the *parietal peritoneum*, covers all the fundus, part of the corpus, but none of the cervix. This incompleteness allows surgical entry into the uterus without incision of the peritoneum, thereby reducing the risk of peritonitis.

The *fallopian tubes*, which extend from the sides of the fundus and terminate near the ovaries, are about 3¼" to 5½" (8 to 14 cm) long. Through ciliary and muscular action, they carry ova from the ovaries to the uterus and facilitate the movement of sperm from the uterus toward the ovaries. Fertilization of the ovum normally occurs

in a fallopian tube. The same ciliary and muscular action helps move a *zygote* (fertilized ovum) down to the uterus, where it implants in the blood-rich inner uterine lining, the endometrium.

The *ovaries* are two almond-shaped organs, one on either side of the fundus, situated behind and below the fallopian tubes. The ovaries produce ova and two primary hormones—estrogen and progesterone—in addition to small amounts of androgen. These hormones, in turn, produce and maintain secondary sex characteristics, prepare the uterus for pregnancy, and stimulate mammary gland development.

The ovaries are connected to the uterus by the utero-ovarian ligament and are divided into two parts: the *cortex*, which contains primordial and graafian follicles in various stages of development, and the *medulla*, which consists primarily of vasculature and loose connective tissue.

A normal female is born with at least 400,000 primordial follicles in her ovaries. At puberty, these ova precursors become graafian follicles, in response to the effects of pituitary gonadotropic hormones: follicle-stimulating hormone (FSH) and luteinizing hormone (LH). In the life cycle of a female, fewer than 500 ova eventually mature and develop the potential for fertilization.

Menstrual cycle

Maturation of the hypothalamus and the resultant increase in hormone levels initiate puberty. In the adolescent girl, breast development—the first sign of puberty—is followed by the appearance of pubic and axillary hair and the characteristic adolescent growth spurt. The reproductive system begins to undergo a series of hormone-induced changes that result in *menarche*, the onset of menstruation (or menses). Menarche usually occurs at about age 13 but may occur anytime between ages 9 and 18. Usually, initial menstrual periods are irregular and anovulatory, but after a year or so, periods generally are more regular.

Three phases

The menstrual cycle consists of three phases: menstrual, proliferative (estrogen-dominated), and secretory (progesterone-dominated). These phases correspond to the phases of ovarian function. The menstrual and proliferative phases correspond to the follicular ovarian phase. The secretory phase corresponds to the luteal ovarian phase. (See [How the menstrual cycle reflects ovarian function.](#))

The *menstrual phase* begins with day 1 of menstruation. During this phase, decreased estrogen and progesterone levels provoke shedding of most of the endometrium. When these hormone levels are low, positive feedback causes the hypothalamus to produce FSH-releasing factor and LH-releasing factor. These two factors, in turn, stimulate pituitary secretion of FSH and LH. FSH stimulates the growth of ovarian follicles; LH stimulates these follicles to secrete estrogen.

The *proliferative phase* begins with the cessation of the menstrual period and ends with ovulation. During this phase, the increased amount of estrogen secreted by the developing ovarian follicles causes the endometrium to proliferate in preparation for possible pregnancy. At about day 14 of a 28-day menstrual cycle (the average length), these high estrogen levels trigger ovulation: the rupture of one of the developing follicles and subsequent release of an ovum.

The *secretory phase* extends from the day of ovulation to about 3 days before the next menstrual period (premenstrual phase). In most women, this final phase of the menstrual cycle lasts 13 to 15 days (the duration of this phase varies less than those of the menstrual and proliferative phases). After ovulation, the ruptured follicle that released the ovum remains under the influence of LH. It then becomes the *corpus luteum* and starts secreting progesterone in addition to estrogen.

Fertilization

In the nonpregnant female, LH controls the secretions of the corpus luteum; in the pregnant female, human chorionic gonadotropin (HCG) controls them. At the end of the secretory phase, the uterine lining is ready to receive and nourish a zygote.

If fertilization doesn't occur, increasing estrogen and progesterone levels decrease FSH and LH production. Because LH is necessary to maintain the corpus luteum, a decrease in LH production causes the corpus luteum to atrophy and stop secreting estrogen and progesterone. The thickened uterine lining then begins to slough off, and menstruation begins again.

If fertilization and pregnancy occur, the endometrium grows even thicker. After implantation of the zygote (about 5 or 6 days after fertilization), the endometrium becomes the *decidua*. Chorionic villi produce HCG soon after implantation, stimulating the corpus luteum to continue secreting estrogen and progesterone, a process

that prevents further ovulation and menstruation.

HCG continues to stimulate the corpus luteum until the *placenta*—the vascular organ that develops to transport materials to and from the fetus—forms and starts producing its own estrogen and progesterone. After the placenta takes over hormonal production, secretions of the corpus luteum are no longer needed to maintain the pregnancy, and the corpus luteum gradually decreases its function and begins to degenerate.

Pregnancy

Cell multiplication and differentiation begin in the zygote at the moment of conception. By about 17 days after conception, the placenta has established circulation to what is now an *embryo* (the term used for the conceptus between the 2nd and 7th weeks of pregnancy). By the end of the embryonic stage, fetal structures are formed. Further development now consists primarily of growth and maturation of already formed structures. From this point until birth, the conceptus is called a *fetus*.

The duration of a normal pregnancy ranges from 240 to 300 days. Although pregnancies vary in duration, they're conveniently divided into three trimesters.

First trimester

During the first trimester, a female usually experiences physical changes, such as amenorrhea, urinary frequency, nausea and vomiting (more severe in the morning or when the stomach is empty), breast swelling and tenderness, fatigue, increased vaginal secretions, and constipation.

Within 10 days of conception, pregnancy tests, which detect HCG in the urine and serum, are usually positive. Although such positive tests strongly suggest pregnancy, a pelvic examination helps confirm it by showing Hegar's sign (cervical and uterine softening), Chadwick's sign (a bluish coloration of the vagina and cervix resulting from increased venous circulation), and an enlarged uterus.

The first trimester is a critical time during pregnancy. Rapid cell differentiation makes the developing embryo or fetus highly susceptible to the teratogenic effects of viruses, alcohol, cigarettes, caffeine, and other drugs.

Second trimester

During the second trimester (from the 13th to the 26th week of pregnancy), uterine and fetal size increase substantially, causing weight gain, a thickening waistline, abdominal enlargement and, possibly, reddish streaks as abdominal skin stretches (striation). In addition, pigment changes may cause skin changes, such as linea nigra, melasma (mask of pregnancy), and a darkening of the areolae of the nipples.

Other physical changes may include diaphoresis, increased salivation, indigestion, continuing constipation, hemorrhoids, nosebleeds, and some dependent edema. The breasts become larger and heavier, and about 19 weeks after the last menstrual period, they may secrete colostrum. By about the 16th to 18th week of pregnancy, the fetus is large enough for the mother to feel it move (quickening).

Third trimester

During the third trimester, the mother feels Braxton Hicks contractions, sporadic episodes of painless uterine tightening that help strengthen uterine muscles in preparation for labor. Increasing uterine size may displace pelvic and intestinal structures, causing indigestion, protrusion of the umbilicus, shortness of breath, and insomnia. The mother may experience backaches because she walks with a swaybacked posture to counteract her frontal weight. Lying on her left side may help minimize the development of varicose veins, hemorrhoids, and ankle edema. This position relieves pressure on the lower vasculature.

Labor and delivery

About 2 to 4 weeks before birth, lightening—the descent of the fetal head into the pelvis—shifts the uterine position. This relieves pressure on the diaphragm and enables the mother to breathe more easily.

Onset of labor characteristically produces low back pain and passage of a small amount of bloody show (although this brownish or blood-tinged plug of cervical mucus may be passed up to 2 weeks before active labor). As labor progresses, the cervix becomes soft, then effaces and dilates; the amniotic membranes may rupture spontaneously, causing a gush or leakage of amniotic fluid. Uterine contractions become increasingly regular, frequent, intense, and longer.

Four stages

Labor is usually divided into four stages (see [Stages of labor](#)):

- u *Stage I*, the longest stage, lasts from onset of regular contractions until full cervical dilation (4" [10 cm]). The average duration of this stage is about 12 hours for a primigravida and 6 hours for a multigravida.
- u *Stage II* lasts from full cervical dilation until delivery of the infant; about 1 to 2 hours for a primigravida, 30 minutes for a multigravida.
- u *Stage III*, the time between delivery and expulsion of the placenta, usually lasts 3 to 4 minutes for a primigravida and 4 to 5 minutes for a multigravida, but may last up to 30 minutes.
- u *Stage IV* constitutes a period of recovery during which homeostasis is reestablished. This final stage lasts 1 to 4 hours after expulsion of the placenta.

Assessment

As with other body systems, thorough assessment of the reproductive system depends on an accurate history and physical examination.

History

A complete history includes information about the patient's overall patterns of health and illness, as well as any history of pregnancy or abortion. Other pertinent data include the date of the patient's last menstrual period, whether her periods are regular or irregular, and the patient's sexual history, including number of partners, frequency, satisfaction, and current method of birth control. The patient's family history, personal medical and surgical history, allergies, and habits, such as smoking or alcohol use, should also be documented.

CULTURAL TIP Encourage the patient to reveal any cultural interpretation of health, illness, and health care.

Common chief complaints associated with gynecologic or obstetric disorders include pain, especially associated with the menstrual cycle or intercourse; abnormal vaginal discharge accompanied by burning or itching; disturbances of the menstrual cycle; infertility; and changes in patterns of urinary elimination. Many disorders produce no symptoms and may be detected only during routine physical examinations.

CULTURAL TIP Be considerate of the patient; members of many cultures are reluctant to talk about sexual matters. Also, in some cultures, sexual matters aren't discussed freely with members of the opposite sex.

Physical examination

This careful examination should include the patient's thyroid gland, heart, lungs, breasts, abdomen, extremities, and pelvis. Measuring vital signs, height, and weight allows comparison with expected values to establish a baseline for the patient. Assessing nutritional status completes the examination.

Sources of pathology

In no other part of the body do so many interrelated physiologic functions occur in such proximity as in the area of the female reproductive tract. Besides the internal genitalia, the female pelvis contains the organs of the urinary and the GI system (bladder, ureters, urethra, sigmoid colon, and rectum). The reproductive tract and its surrounding areas are thus the site of urination, defecation, menstruation, ovulation, copulation, impregnation, and parturition. It's easy to understand how an abnormality in one pelvic organ can readily induce abnormality in another.

When conducting a pelvic examination, therefore, you must consider all possible sources of pathology. Remember that some serious abnormalities of the pelvic organs can be asymptomatic. Remember, too, that some abnormal findings in the pelvic area may result from pathologic changes in other organ systems, such as the upper urinary and the GI tracts, the endocrine glands, and the neuromusculoskeletal system. Pain symptoms are often associated with the menstrual cycle; therefore, in many common diseases of the female reproductive tract, such pain follows a cyclic pattern. A patient with pelvic inflammatory disease, for example, may complain of increasing premenstrual pain that is relieved by onset of menstruation.

Stages of labor

After onset of regular uterine contractions, the head of the fetus is engaged in the mother's pelvis. It ends when the placenta is delivered.

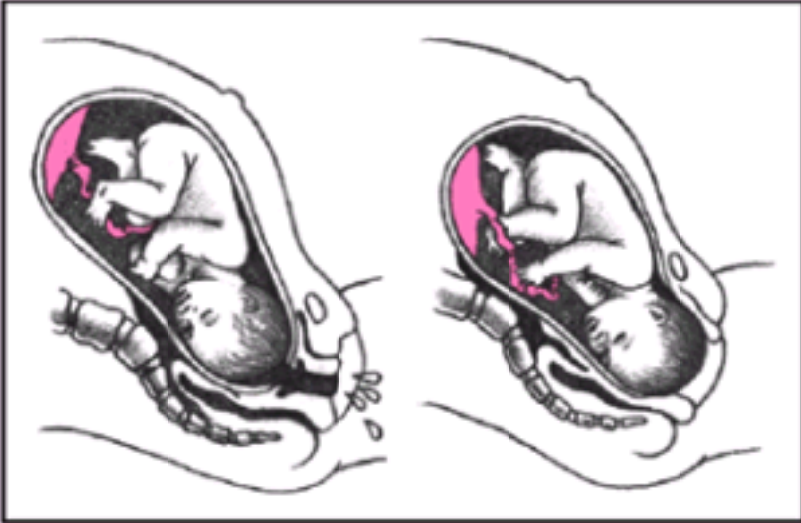

Lightening

About 2 to 4 weeks before birth and before the onset of regular contractions, the fetal head descends into the pelvis.

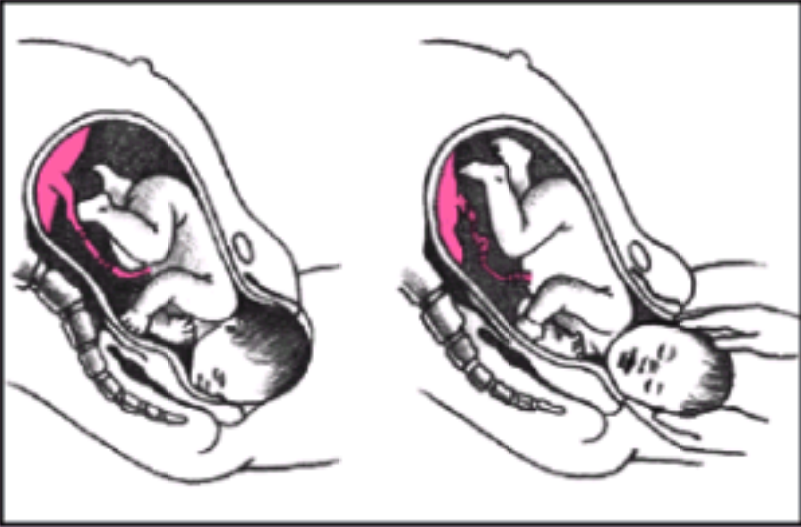

Stage I

In this stage, the onset of regular contractions and rupture of the amniotic sac proceed to full cervical dilation.

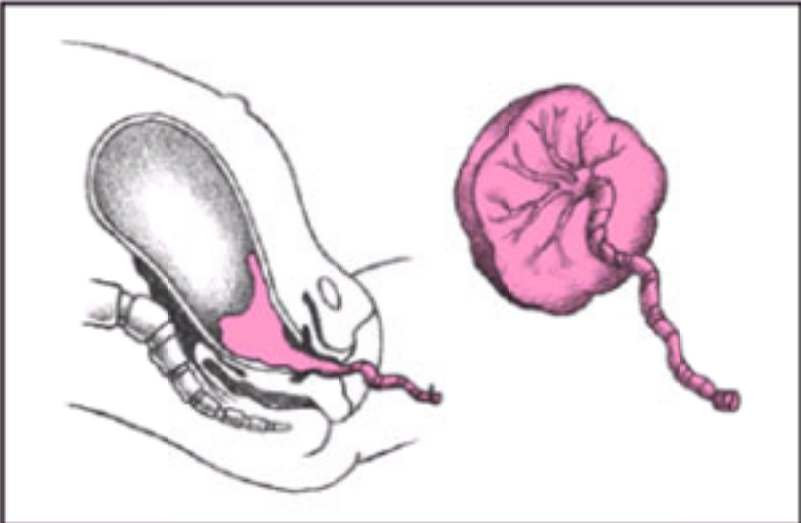

Stage II

This stage lasts from full cervical dilation until delivery of the neonate. Delivering the head and rotating the head are shown here.

Stage III

The time between delivery and expulsion of the placenta makes up stage III.

Stage IV

Reestablishment of homeostasis during this stage includes recuperation from the anesthetic (if used), normalization of vital signs, cessation of bleeding, and return of muscle tone.

Pelvic examination

A pelvic examination and a thorough patient history are essential for any patient with symptoms related to the reproductive tract or adjacent body systems. Document any history of pregnancy, miscarriage, and abortion. Ask the patient if she has experienced any recent changes in her urinary habit or menstrual cycle. If she practices birth control, find out what method she uses and whether she has experienced any adverse effects.

Then prepare the patient for the pelvic examination as follows:

- u Ask the patient if she has douched within the last 24 hours. Explain that douching washes away cells or organisms that the examination is intended to evaluate.
- u Check weight and blood pressure.
- u For the patient's comfort, instruct her to empty her bladder before the examination. Provide a urine specimen container, if needed.
- u To help the patient relax, which is essential for a thorough pelvic examination, explain what the examination entails and why it's necessary.
- u If the patient is scheduled for a Papanicolaou (Pap) test, inform her that another smear may have to be taken later if there are abnormal findings with the first test. Reassure her that this is done to confirm the results of the first test. If she has never had a Pap test before, tell her it's painless.
- u After the Pap test, a bimanual examination is performed to assess the size and location of the ovaries and uterus.
- u After the examination, offer the patient premoistened tissues to clean the vulva.

Diagnostic tests

To diagnose gynecologic disorders, diagnostic tests include the following studies, which can be performed in an outpatient setting:

- u wet smear to examine vaginal secretions for specific organisms, such as *Trichomonas vaginalis*, *Candida albicans*, or *Haemophilus vaginalis*, or to evaluate semen specimens in rape or infertility cases
- u endometrial biopsy to assess hormonal secretions of the corpus luteum, determine whether normal ovulation is occurring, and check for neoplasia
- u hysteroscopy, as an adjunct to endometrial biopsy, used with laparoscopy to directly view the uterus and to confirm uterine fibroid tumors and adhesions
- u dilatation and curettage to evaluate atypical bleeding and detect carcinoma
- u echostereoscopy, which combines ultrasonography with hysteroscopy, to visualize internal structures and detect abnormalities
- u laparoscopy, to evaluate infertility, dysmenorrhea, and pelvic pain and as a means of sterilization, which can be performed only in a facility while the patient is under anesthesia.

CULTURAL TIP Use interpreters as needed to gather information and gain cooperation from patients. In some facilities, it's also necessary to have a female present while the patient is examined.

Gynecologic disorders

Common gynecologic complaints may arise from menstrual problems, such as premenstrual syndrome, and infections, such as vulvovaginitis and pelvic inflammatory disease. Hormonal dysfunction can lead to other gynecologic disorders, such as endometriosis and infertility. The development of benign tumors can account for such disorders as ovarian cysts and uterine leiomyomas.

ENDOMETRIOSIS

When endometrial tissue appears outside the lining of the uterine cavity, endometriosis results. Such ectopic tissue is generally confined to the pelvic area, most commonly around the ovaries, uterovesical peritoneum, uterosacral ligaments, and the cul-de-sac, but it can appear anywhere in the body.

This ectopic endometrial tissue responds to normal stimulation in the same way that the endometrium does. During menstruation, the ectopic tissue bleeds, which causes inflammation of the surrounding tissues. This inflammation causes fibrosis, leading to adhesions, which produce pain and infertility.

Active endometriosis usually occurs between ages 30 and 40, especially in women who postpone childbearing; it's uncommon before age 20. Severe symptoms of endometriosis may have an abrupt onset or may develop over many years. This disorder usually becomes progressively severe during the menstrual years but tends to subside after menopause.

Causes and pathophysiology

The direct cause is unknown, but familial susceptibility or recent hysterotomy may predispose a woman to endometriosis. Although neither of these possible predisposing factors explains all the lesions in endometriosis or their location, research focuses on the following possible causes:

- u *Transportation* (retrograde menstruation). During menstruation, the fallopian tubes expel endometrial fragments that implant outside the uterus.
- u *Formation in situ*. Inflammation or a hormonal change triggers metaplasia.
- u *Induction* (a combination of transportation and formation in situ). The endometrium chemically induces undifferentiated mesenchyma to form endometrial epithelium. (This is the most likely cause.)
- u *Immune system defects*. Endometriosis may result from a specific defect in cell-mediated immunity. Researchers have documented higher titers of antibodies to endometrial antigens in patients with this disorder.

Complications

The primary complication of endometriosis is infertility. Other complications include spontaneous abortion, anemia due to excessive bleeding, and emotional problems due to infertility.

Assessment findings

The patient may complain of cyclic pelvic pain, infertility, and acquired dysmenorrhea. The patient typically reports pain in the lower abdomen, vagina, posterior pelvis, and back. This pain usually begins from 5 to 7 days before menses, reaches a peak, and lasts for 2 to 3 days. It differs from primary dysmenorrhea pain, which is more cramplike and concentrated in the abdominal midline. The severity of pain doesn't necessarily indicate the extent of the disease.

Other clinical features depend on the ectopic tissue site. The patient may report a history of infertility and profuse menses (oviducts and ovaries). She may complain of deep-thrust dyspareunia (ovaries and cul-de-sac); suprapubic pain, dysuria, and hematuria (bladder); painful defecation, rectal bleeding with menses, and pain in the coccyx or sacrum (rectovaginal septum and colon); nausea and vomiting that worsen before menses and abdominal cramps (small bowel and appendix).

Palpation may disclose multiple tender nodules on uterosacral ligaments or in the rectovaginal septum. These nodules enlarge and become more tender during menses. Palpation may also uncover ovarian enlargement in the presence of endometrial cysts on the ovaries or thickened, nodular adnexa (as in pelvic inflammatory disease).

Diagnostic tests

Laparoscopy is used to confirm the diagnosis and identify the stage of the disease. A scoring and staging system created by the American Fertility Society quantifies endometrial implants according to size, character, and location. Stage I is minimal disease (0 to 5 points); Stage II signifies mild disease (6 to 15 points); Stage III, moderate disease (16 to 40 points); and Stage IV, severe disease (more than 40 points).

Differential diagnosis of endometriosis is conducted to rule out chronic pelvic inflammatory disease, hemorrhagic corpus luteum cyst, malignant or ovarian neoplasm, ectopic pregnancy, recurrent acute salpingitis, and adenomyosis. These disorders can mimic signs and symptoms of endometriosis.

Treatment

The stage of the disease and the patient's age and desire to have children are considered in determining the course of treatment.

Conservative therapy for young women who want to have children includes androgens, such as danazol, which produce a temporary remission in Stages I and II. Progestins and oral contraceptives also relieve symptoms. Newer treatment involves gonadotropin-releasing analogues, which suppress estrogen production. This causes atrophic changes in the ectopic endometrial tissue, which allows healing.

Laparoscopy, used for diagnostic purposes, can also be used therapeutically to lyse adhesions, remove small implants, and cauterize implants. Laparoscopy also permits laser vaporization of implants. This surgery is usually followed with hormonal therapy to suppress the return of endometrial implants.

When the patient has ovarian masses, surgery may be needed to rule out cancer. Conservative surgery is possible, but the treatment of choice for women who don't want to bear children or for extensive disease (Stages III and IV) is a total abdominal hysterectomy with bilateral salpingo-oophorectomy.

Minor gynecologic procedures are contraindicated immediately before and during menstruation.

Nursing diagnoses

u Anxiety u Body image disturbance u Chronic pain u Fear u Ineffective individual coping u Knowledge deficit u Risk for infection u Sexual dysfunction

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will express feelings about self.
- u The patient will remain free from signs and symptoms of infection.
- u The patient and family members will express understanding of the disorder and treatment.
- u The patient will develop adequate coping behaviors.

Nursing interventions

- u Encourage the patient and her partner to verbalize their feelings about the disorder and its effect on their relationship. Offer emotional support. Stress the need for open communication before and during intercourse to minimize discomfort and frustration.
- u Help the patient to develop effective coping strategies. Refer her and her partner to a mental health professional for additional counseling, if necessary. Encourage her to contact a support group, such as the Endometriosis Association.

Patient teaching

- u Explain all procedures and treatment options. Clarify any misconceptions about the disorder, associated complications, and fertility.
- u Advise adolescents to use sanitary napkins instead of tampons. This can help prevent retrograde flow in girls with a narrow vagina or small vaginal meatus.
- u Because infertility is a possible complication, counsel the patient who wants children not to postpone childbearing.
- u Advise the patient to have an annual pelvic examination and a Pap test.

FEMALE INFERTILITY

Infertility is the inability to conceive after regular intercourse for at least 1 year without contraception. Infertility affects 10% to 15% of all couples in the United States. Following extensive investigation and treatment, about half of infertile couples achieve pregnancy. Of the half who don't, roughly 10% have no pathologic basis for infertility; the prognosis in this group becomes extremely poor if pregnancy isn't achieved after 3 years.

Causes and pathophysiology

Female infertility may result from functional, anatomic, or psychological causes.

Functional causes

Complex hormonal interactions enable the normal function of the female reproductive tract and require an intact hypothalamic-pituitary-ovarian mechanism, a system that stimulates and regulates the hormones needed for normal sexual development and function. Malfunction of this mechanism can cause infertility.

The ovary controls, and is controlled by, the hypothalamus through a system of negative and positive feedback mediated by estrogen production. Insufficient gonadotropin levels (both luteinizing and follicle-stimulating hormones) may result from infections, tumors, or neurologic disease of the hypothalamus or pituitary gland. Hypothyroidism also impairs fertility.

Anatomic causes

Possible anatomic causes of infertility include:

- u *Ovarian factors* are related to anovulation and oligo-ovulation (infrequent ovulation) and are a major cause of infertility. Pregnancy or direct visualization provides irrefutable evidence of ovulation. Presumptive signs of ovulation include regular menses, cyclic changes reflected in basal body temperature readings, postovulatory progesterone levels, and endometrial changes due to the presence of progesterone. Absence of presumptive signs suggests anovulation.

Ovarian failure, in which no ova are produced by the ovaries, may result from ovarian dysgenesis or premature menopause. Amenorrhea is often associated with ovarian failure. Oligo-ovulation may result from a mild hormonal imbalance in gonadotropin production and regulation, which may be caused by polycystic ovary disease or abnormalities in the adrenal or thyroid gland that adversely affect hypothalamic- pituitary functioning.

- u *Uterine abnormalities* may include congenitally absent uterus, bicornuate or double uterus, leiomyomas, or Asherman's syndrome, in which the anterior and posterior uterine walls adhere because of scar tissue formation.

u *Tubal and peritoneal factors* are due to faulty tubal transport mechanisms and unfavorable environmental influences affecting the sperm, ova, or recently fertilized ovum. Tubal loss or impairment may occur secondary to ectopic pregnancy.

In many cases, tubal and peritoneal factors result from anatomic abnormalities: bilateral occlusion of the tubes due to salpingitis (resulting from gonorrhea, tuberculosis, or puerperal sepsis); peritubal adhesions (resulting from endometriosis, pelvic inflammatory disease, use of an intrauterine device for contraception, diverticulosis, or childhood rupture of the appendix); and uterotubal obstruction due to tubal spasm.

u *Cervical factors* may include a malfunctioning cervix that produces deficient or excessively viscous mucus that is impervious to sperm, preventing entry into the uterus. In cervical infection, viscous mucus may contain spermicidal macrophages. The possible existence of cervical antibodies that immobilize sperm is also under investigation.

Psychological causes

Relatively few cases of infertility result from psychological problems. Occasionally, ovulation may stop under stress due to failure of luteinizing hormone release. More often, however, psychological problems result from, rather than cause, infertility.

Complications

Associated complications include psychosocial problems.

Assessment findings

The patient's history indicates the inability to conceive after at least 1 year of regular intercourse without contraception. The patient may also report irregular, painless menses, which may indicate anovulation, or a history of pelvic inflammatory disease, which may suggest fallopian tube blockage.

Differential medical diagnosis includes anorexia nervosa, bulimia, neoplasms, congenital anomalies, drug ingestion, polycystic ovarian disease, hypothyroidism, and hypothalamic disease.

Diagnostic tests

Basal body temperature graph shows a sustained elevation in body temperature postovulation until just before onset of menses, indicating the approximate time of ovulation.

Endometrial biopsy, done on or about day 5 after the basal body temperature elevates, provides histologic evidence that ovulation has occurred.

Progesterone blood levels measured when they should be highest can show a luteal phase deficiency. Over-the-counter ovulation predictors are less expensive and quite accurate.

Hysterosalpingography provides radiologic evidence of tubal obstruction and uterine cavity abnormalities.

Endoscopy confirms the results of hysterosalpingography and visualizes the endometrial cavity by hysteroscopy or explores the posterior surface of the uterus, fallopian tubes, and ovaries by culdoscopy.

Laparoscopy allows visualization of the abdominal and pelvic areas.

In postcoital examination, the cervical mucus is examined for motile sperm cells following intercourse that takes place at midcycle (as close to ovulation as possible).

Immunologic or antibody testing allows detection of spermicidal antibodies in the sera of the female.

Treatment

Identification of the underlying abnormality or dysfunction is considered to determine the appropriate treatment.

u In hyperactivity or hypoactivity of the adrenal or thyroid gland, hormonal therapy is necessary; progesterone deficiency requires progesterone replacement. Anovulation necessitates treatment with clomiphene citrate, human menopausal gonadotropins, or human chorionic gonadotropin; ovulation usually occurs several days after such administration. If mucus production decreases (an adverse effect of clomiphene citrate), small doses of estrogen to improve the quality of cervical mucus may be given concomitantly.

u Surgical restoration may correct certain anatomic causes of infertility, such as fallopian tube obstruction. Surgery may also be necessary to remove tumors located within or near the hypothalamus or pituitary gland.

u Endometriosis requires drug therapy (danazol, medroxyprogesterone, or noncyclic administration of oral contraceptives); surgical removal of areas of endometriosis; or a combination of both.

u Other options, often controversial and involving emotional and financial cost, include surrogate mothering, frozen embryos, in vitro fertilization, and gamete intra-fallopian transfer.

Nursing diagnoses

u Altered sexuality patterns u Anxiety u Body image disturbance u Dysfunctional grieving u Hopelessness u Ineffective family coping: Disabling u Ineffective individual coping u Knowledge deficit u Powerlessness u Self-esteem disturbance

Key outcomes

- u The patient will communicate feelings about the current situation.
- u The patient will be involved in planning her own care.
- u The patient will express feelings of having greater control over the current situation.
- u The patient will use available support systems, such as family and friends, to aid in coping.
- u The patient will express positive feelings about self.

Nursing interventions

- u Help the couple cope effectively with feelings of anxiety, hopelessness, and powerlessness by explaining all procedures thoroughly. Help boost the patients' self-esteem by encouraging them to talk about their feelings. Listen nonjudgmentally and with empathy.
- u Help the couple develop effective coping strategies. Refer them to a mental health counselor, if needed.
- u Encourage the couple to join community support groups for infertile couples, if appropriate.

Patient teaching

- u Teach the couple about normal reproductive anatomy and physiology and how theirs may differ.
- u Explain all procedures and treatment options to help the couple make informed decisions. If surgery is required, explain what to expect after surgery.

OVARIAN CYSTS

Usually nonneoplastic, ovarian cysts are sacs on an ovary. These cysts contain fluid or semisolid material. They are usually small and produce no symptoms, but they require thorough investigation as possible sites of malignant change. Common ovarian cysts include follicular cysts, lutein cysts (granulosa-lutein, corpus luteum, and theca-lutein cysts), and polycystic (or sclerocystic) ovarian disease. Ovarian cysts can develop anytime between puberty and menopause, including during pregnancy. Granulosa-lutein cysts occur infrequently, usually during early pregnancy. The prognosis for nonneoplastic cysts is excellent.

Causes and pathophysiology

Follicular cysts are usually small and arise from follicles that overdistend instead of going through the atretic stage of the menstrual cycle. They appear semitransparent and are filled with a watery fluid visible through their thin walls. When such cysts persist into menopause, they secrete excessive amounts of estrogen in response to the hypersecretion of follicle-stimulating hormone and luteinizing hormone that normally occurs during menopause.

Granulosa-lutein cysts, which occur within the corpus luteum, are functional, nonneoplastic enlargements of the ovaries, caused by excessive accumulation of blood during menstruation.

Theca-lutein cysts are commonly bilateral and filled with clear, straw-colored fluid; they're often associated with hydatidiform mole, choriocarcinoma, or hormone therapy (with human chorionic gonadotropin [HCG] or clomiphene citrate).

Polycystic ovarian disease is part of the Stein-Leventhal syndrome and stems from endocrine abnormalities.

Complications

Possible complications include amenorrhea, oligomenorrhea, secondary dysmenorrhea, and infertility. Torsion of the ovary and fallopian tube may result in rupture of the cyst with resulting peritonitis or intraperitoneal hemorrhage, shock, and death.

Assessment findings

Small ovarian cysts (such as follicular cysts) usually don't produce symptoms unless torsion or rupture occurs. The patient may report mild pelvic discomfort, low back pain, dyspareunia, or abnormal uterine bleeding secondary to a disturbed ovulatory pattern. Inspection may reveal signs of an acute abdomen similar to signs of appendicitis (abdominal tenderness, distention, and rigidity).

Granulosa-lutein cysts that appear early in pregnancy may grow as large as 2" to 2½" (5.1 to 6.4 cm) in diameter and produce unilateral pelvic discomfort. If rupture occurs, massive intraperitoneal hemorrhage may result. A nonpregnant patient may report delayed menses, followed by prolonged or irregular bleeding.

Palpation may disclose enlarged ovaries caused by lack of ovulation. It may also reveal large follicular cysts. Theca-lutein cysts usually aren't palpable.

Diagnostic tests

Visualization of the ovary through ultrasonography, laparoscopy, or surgery (often for another condition) confirms ovarian cysts. The following tests provide additional diagnostic information:

- u HCG titers that are extremely elevated strongly suggest theca-lutein cysts.
- u Urine 17-ketosteroid concentrations that are slightly elevated accompany polycystic ovarian disease.
- u Basal body temperature graphs and endometrial biopsy results indicate anovulation.
- u Direct visualization is used to rule out paraovarian cysts of the broad ligament, salpingitis, endometriosis, and neoplastic cysts.

Treatment

Follicular cysts generally don't require treatment because they tend to disappear spontaneously by reabsorption or silent rupture within 60 days. If follicular cysts interfere with daily activities, administration of oral clomiphene citrate or I.M. progesterone for 5 days reestablishes the ovarian hormonal cycle. Oral contraceptives are used to accelerate involution of functional cysts (including both types of lutein cysts and follicular cysts).

Treatment for patients with granulosa-lutein cysts that occur during pregnancy is based on the patient's symptoms because these cysts diminish during the third trimester and rarely require surgery. Theca-lutein cysts disappear spontaneously after elimination of the hydatidiform mole, destruction of choriocarcinoma, or discontinuation of HCG or clomiphene citrate therapy.

Treatment for patients with polycystic ovarian disease may include clomiphene citrate to induce ovulation, medroxyprogesterone acetate for 10 days of every month for the patient who doesn't want to become pregnant, or low-dose oral contraceptives for the patient who needs reliable contraception.

If an ovarian cyst is persistent or suspicious, surgery in the form of laparoscopy or exploratory laparoscopy with possible ovarian cystectomy or oophorectomy may be needed.

Nursing diagnoses

- u Altered sexuality patterns
- u Anxiety
- u Fluid volume deficit
- u Ineffective individual coping
- u Knowledge deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient's vital signs will remain within normal parameters.
- u The patient's fluid volume will remain normal.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express feelings of comfort.
- u The patient and spouse will express feelings about the condition and its effect on the relationship.

Nursing interventions

- u Before surgery, watch for signs of cyst rupture, such as increasing abdominal pain, distention, and rigidity. Monitor vital signs for fever, tachypnea, or hypotension, a sign of possible peritonitis or intraperitoneal hemorrhage. Administer sedatives, as ordered, to ensure adequate preoperative rest.
- u After surgery, encourage frequent movement in bed and early ambulation.
- u Encourage the patient to discuss her feelings, provide emotional support, and help her develop effective coping strategies.

Patient teaching

- u Carefully explain the nature of the particular cyst, the type of discomfort the patient experiences, and how long the condition may last.
- u Before discharge, advise the patient to increase her at-home activity gradually, preferably over 4 to 6 weeks. Tell her to abstain from intercourse, using tampons, and douching during this time.

PELVIC INFLAMMATORY DISEASE

Pelvic inflammatory disease (PID) is an umbrella term that refers to any acute, subacute, recurrent, or chronic infection of the oviducts and ovaries, with adjacent tissue involvement. It includes inflammation of the cervix (cervicitis), uterus (endometritis), fallopian tubes (salpingitis), and ovaries (oophoritis), which can extend to the connective tissue lying between the broad ligaments (parametritis). (See [Forms of pelvic inflammatory disease: Features and test findings.](#))

About 60% of cases result from overgrowth of one or more of the common bacterial species found in the cervical mucus. Early diagnosis and treatment help prevent damage to the reproductive system, as does well-planned nursing care. Untreated PID may be fatal.

Causes

PID can result from infection with aerobic or anaerobic organisms. The organisms *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are the most common causes because they most readily penetrate the bacteriostatic barrier of cervical mucus.

Common bacteria found in cervical mucus include staphylococci, streptococci, diphtheroids, chlamydiae, and coliforms, including *Pseudomonas* and *Escherichia coli*. Uterine infection can result from any one or several of these organisms or may follow the multiplication of normally nonpathogenic bacteria in an altered endometrial environment. Bacterial multiplication is most common during parturition because the endometrium is atrophic, quiescent, and not stimulated by estrogen.

Risk factors include:

- any sexually transmitted infection
- multiple sex partners
- conditions or procedures, such as conization or cauterization of the cervix, that alter or destroy cervical mucus, allowing bacteria to ascend into the uterine cavity
- any procedure that risks transfer of contaminated cervical mucus into the endometrial cavity by an instrument, such as a biopsy curet or an irrigation catheter, or by tubal insufflation or abortion or recent intrauterine device insertion
- infection during or after pregnancy
- infectious foci within the body, such as drainage from a chronically infected fallopian tube, a pelvic abscess, a ruptured appendix, or diverticulitis of the sigmoid colon
- cigarette smoking
- multiparity
- douching
- intercourse during menses.

ADVANCED PRACTICE

<div>Forms of pelvic inflammatory disease: Features and test findings</div>	
CLINICAL FEATURES	DIAGNOSTIC FINDINGS
<p>Salpingo-oophoritis</p> <ul style="list-style-type: none">▫ <i>Acute</i>: sudden onset of lower abdominal and pelvic pain, usually following menses; increased vaginal discharge; fever; malaise; lower abdominal pressure and tenderness; tachycardia; pelvic peritonitis▫ <i>Chronic</i>: recurring acute episodes	<ul style="list-style-type: none">▫ Blood studies show leukocytosis—or a normal white blood cell (WBC) count.▫ X-rays may show ileus.▫ Pelvic examination reveals extreme tenderness.▫ Smear of cervical or periurethral gland exudate shows gram-negative intracellular diplococci.
<p>Cervicitis</p> <ul style="list-style-type: none">▫ <i>Acute</i>: purulent, foul-smelling vaginal discharge; vulvovaginitis, with itching or burning; red, edematous cervix; pelvic discomfort; sexual dysfunction; menorrhagia; infertility; spontaneous abortion▫ <i>Chronic</i>: cervical dystocia, laceration or eversion of the cervix, ulcerative vesicular lesion (when cervicitis results from herpes simplex virus [HSV] 2)	<ul style="list-style-type: none">▫ <i>Chlamydia trachomatis</i> is the most common organism infecting the cervix, followed by <i>Neisseria gonorrhoea</i>, which occurs with <i>C. trachomatis</i> about 40% of the time. HSV and human papillomavirus are other common causes.▫ Cytologic smears may reveal severe inflammation.▫ If cervicitis isn't complicated by salpingitis, WBC count is normal or slightly elevated; erythrocyte sedimentation rate (ESR) is elevated.▫ In <i>acute cervicitis</i>, cervical palpation reveals tenderness.▫ In <i>chronic cervicitis</i>, causative organisms are usually staphylococcus or streptococcus.
<p>Endometritis (generally postpartum or postabortion)</p> <ul style="list-style-type: none">▫ <i>Acute</i>: mucopurulent or purulent vaginal discharge oozing from the cervix; edematous, hyperemic endometrium, possibly leading to ulceration and necrosis (with virulent organisms); lower abdominal pain and tenderness; fever; rebound pain; abdominal muscle spasm; thrombophlebitis of uterine and pelvic vessels (in severe forms)▫ <i>Chronic</i>: recurring acute episodes (increasingly common because of widespread use of intrauterine devices)	<ul style="list-style-type: none">▫ In severe infection, palpation may reveal a boggy uterus.▫ Uterine and blood samples are positive for a causative organism, usually staphylococcus.▫ WBC count and ESR are elevated.

Complications

Possible complications of PID may include potentially fatal septicemia from a ruptured pelvic abscess, pulmonary emboli, infertility, and shock.

Assessment findings

The patient with PID may complain of profuse, purulent vaginal discharge, sometimes accompanied by low-grade fever and malaise (particularly if gonorrhea is the cause). She may also describe lower abdominal pain and vaginal bleeding. Vaginal examination may reveal pain during movement of the cervix or palpation of the adnexa.

Diagnostic tests

Gram stain of secretions from the endocervix or cul-de-sac indicates the causative agent.

Culture and sensitivity testing aids selection of the appropriate antibiotic. Urethral and rectal secretions may also be cultured.

C-reactive protein, a blood test to detect inflammation, is highly sensitive for detecting PID and aids diagnosis.

Ultrasonography, computed tomography scanning, and magnetic resonance imaging may help to identify and locate an adnexal or uterine mass.

Culdocentesis is used to obtain peritoneal fluid or pus for culture and sensitivity testing.

Diagnostic laparoscopy is used to identify fluid in the cul-de-sac, tubal distention, and masses in pelvic abscess and is indicated if the diagnosis is uncertain or if the patient is unresponsive to therapy.

Differential diagnosis should rule out ectopic pregnancy, ruptured corpus lutein cyst, pyelonephritis, appendicitis, endometriosis, adrenal mass tension, or leiomyoma degeneration.

Treatment

To prevent progression of PID, antibiotic therapy begins immediately after culture specimens are obtained. Such therapy can be reevaluated as soon as laboratory results are available (usually after 24 to 48 hours). Infection may become chronic if treated inadequately.

The Centers for Disease Control and Prevention recommends inpatient antibiotic therapy for PID. This includes doxycycline alone or a combination of clindamycin and gentamicin. Outpatient therapy consists of a single dose of cefoxitin given concurrently with probenecid or a single dose of ceftriaxone. Each of these regimens is given with doxycycline.

Supplemental treatment for patients with PID may include bed rest, analgesics, and I.V. fluids as needed.

Development of a pelvic abscess necessitates adequate drainage. A ruptured pelvic abscess is a life-threatening condition. If this complication develops, the patient may need a total abdominal hysterectomy with bilateral salpingo-oophorectomy.

Nursing diagnoses

u Altered sexuality patterns u Anxiety u Fluid volume deficit u Ineffective individual coping u Knowledge deficit u Pain u Risk of infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient's vital signs will remain stable.
- u The patient's fluid volume will remain within normal parameters.
- u The patient will express feelings about current condition.

Nursing interventions

- u After establishing that the patient has no drug allergies, administer antibiotics and analgesics as ordered.
- u Monitor vital signs for fever and fluid intake and output for signs of dehydration. Watch for abdominal rigidity and distention, possible signs of developing peritonitis.
- u Provide frequent perineal care if vaginal drainage occurs.
- u Use meticulous hand-washing technique; institute wound and skin precautions, if necessary.
- u Encourage the patient to discuss her feelings, offer emotional support, and help her develop effective coping strategies.

Patient teaching

- u To prevent recurrence, encourage compliance with treatment and explain the disease and its severity.
- u Stress the need for the patient's sexual partner to be examined and, if necessary, treated for infection.
- u Discuss the use of condoms to prevent the spread of sexually transmitted diseases.
- u Because PID may cause dyspareunia, advise the patient to check with her doctor regarding sexual activity.
- u To prevent infection after minor gynecologic procedures, such as dilatation and curettage, tell the patient to immediately report any fever, increased vaginal discharge, or pain. After such procedures, instruct her to avoid douching or intercourse for at least 7 days.

PREMENSTRUAL SYNDROME

Premenstrual syndrome (PMS) is characterized by a group of somatic, behavioral, cognitive, and mood symptoms that appears 1 to 10 days before menses and usually subsides with its onset. Its effects range from minimal discomfort to severe, disruptive symptoms and can include anxiety, irritability, depression, and multiple somatic complaints.

Reportedly, 70% to 90% of women experience PMS sometime during their childbearing years, usually between ages 25 and 45.

Causes

PMS has been linked to physiologic, psychological, and sociocultural factors. It may result from a progesterone deficiency in the luteal phase of the ovarian cycle. Failure to identify a specific disorder with the specific mechanism suggests PMS, which encompasses a variety of manifestations triggered by normal physiologic hormonal changes.

Complications

Women affected by PMS may experience psychosocial complications, such as reduced self-esteem, depression, and the inability to function in home, work, or school settings.

Assessment findings

The patient's history may include behavioral changes, ranging from mild to severe personality changes, nervousness, hostility, irritability, agitation, sleep disturbances, fatigue, lethargy, and depression. The patient may also report breast tenderness or swelling, abdominal tenderness or bloating, joint pain, headache, edema, diarrhea or constipation, and exacerbations of skin, respiratory, or neurologic problems.

Diagnostic tests

A daily symptom calendar (in which the patient records menstrual symptoms and body temperature for two to three menstrual cycles) is the single most useful tool in diagnosing PMS.

Blood studies may be used to rule out anemia, thyroid disease, or other hormonal imbalances.

A psychological evaluation may be used to rule out or detect an underlying psychiatric disorder.

Treatment

Education and reassurance that PMS is a real, physiologic syndrome are vital parts of treatment. The goal of treatment is to relieve the patient's symptoms. Initial interventions may focus on lifestyle changes, such as eating a diet low in simple sugars, caffeine, and salt; increasing calcium intake; increasing aerobic exercise; reducing stress; and practicing relaxation techniques.

Treatment may include antidepressants; vitamins, such as B complex; progestins; prostaglandin inhibitors; and nonsteroidal anti-inflammatory drugs.

Nursing diagnoses

⌞ Altered family processes ⌞ Altered role performance ⌞ Altered sexuality patterns ⌞ Anxiety ⌞ Body image disturbance ⌞ Fluid volume excess ⌞ Impaired social interaction ⌞ Ineffective individual coping ⌞ Knowledge deficit ⌞ Pain ⌞ Situational low self-esteem

Key outcomes

- ⌞ The patient will express understanding of the relationship between emotional state and behavior.
- ⌞ The patient will become actively involved in planning her own care.
- ⌞ The patient will identify effective and ineffective coping techniques.
- ⌞ The patient will use available support systems, such as family, friends, and groups, to develop and maintain effective coping skills.
- ⌞ The patient will express feelings of comfort.
- ⌞ The patient will express positive feelings about self.

Nursing interventions

- ⌞ Encourage the patient and family members to express their feelings. Offer emotional support and reassurance that the patient's mood changes are related to the disorder and can be controlled with treatment.
- ⌞ Help the patient develop coping strategies. If necessary, refer her for psychological counseling and refer her and her partner for sexual counseling.
- ⌞ Consult a dietitian to provide a diet low in salt, caffeine, and fat and high in complex carbohydrates.
- ⌞ Encourage the patient to drink adequate fluids to promote diuresis and decrease bloating and edema.
- ⌞ Provide comfort measures to relieve pain.

Patient teaching

- ⌞ Discuss lifestyle changes that might alleviate symptoms. Advise further medical consultation if severe symptoms disrupt the patient's lifestyle.
- ⌞ Point out that self-help groups exist for women with PMS. If appropriate, help her to contact such a group.

UTERINE LEIOMYOMAS

Uterine leiomyomas are the most common benign tumors in women. These smooth-muscle tumors are usually multiple and generally occur in the uterine corpus, although they may appear on the cervix or on the round or broad ligament. Also known as myomas or fibromyomas, uterine leiomyomas are commonly called fibroids, but this term is misleading because leiomyomas consist of muscle cells and not fibrous tissue.

Uterine leiomyomas occur in about 20% of all women over age 35 and affect blacks three times more often than whites. Malignant tumors (leiomyosarcomas) develop from benign tumors in only about 0.1% of patients.

Causes and pathophysiology

The cause of uterine leiomyomas is unknown, but excessive levels of estrogen and growth hormone (GH) may influence tumor formation by stimulating susceptible fibromuscular elements. Large doses of estrogen and the later stages of pregnancy increase both tumor size and GH levels. Conversely, uterine leiomyomas usually shrink or disappear after menopause, when estrogen production decreases.

Complications

Possible complications include infertility, anemia from excessive bleeding, and possible intestinal obstruction if the tumors are large or twist around nearby organs. If the patient is pregnant, a leiomyoma may cause spontaneous abortion, premature labor, and dystocia.

Assessment findings

Usually, the patient's history reveals submucosal hypermenorrhea (the cardinal sign of uterine leiomyomas), although other forms of abnormal endometrial bleeding, as well as dysmenorrhea, are possible.

The patient may complain of pain if the tumors twist or degenerate after circulatory occlusion or infection or if the uterus contracts in an attempt to expel a pedunculated submucous leiomyoma. She may also report increasing abdominal girth without weight gain, a feeling of heaviness in the abdomen, constipation, and urinary frequency or urgency if the tumors press on surrounding organs. However, most women with leiomyomas are asymptomatic.

Palpation of the uterus may reveal irregular uterine enlargement, often asymptotically. Palpation of the tumor may find a round or irregular mass.

Ovarian neoplasm, pregnancy, ectopic pregnancy, tube-ovarian inflammatory mass, and diverticular inflammatory mass can mimic symptoms of uterine leiomyomas and need to be differentiated in diagnosis.

Diagnostic tests

Blood studies show anemia from abnormal bleeding. Ultrasonography, dilatation and curettage, and submucosal hysterosalpingography may detect submucosal leiomyomas. Laparoscopy visualizes subserous leiomyomas on the uterine surface. Diagnostic hysteroscopy involves the use of endoscopic equipment to directly view leiomyomas in the endocervical canal and lower uterine segment.

Treatment

Medical management of uterine leiomyomas depends on the severity of symptoms, the size and location of the tumors, and the patient's age, parity, pregnancy status, desire to have children, and general health. Treatment options include:

- ⌞ pelvic examination every 4 to 6 months to monitor the growth of small leiomyomas that produce no symptoms
- ⌞ surgical removal and administering gonadotropin-releasing hormone analogues. These drugs are capable of rapidly suppressing pituitary gonadotropin release, leading to profound hypoestrogenemia and a 50% reduction in uterine volume. Peak effect is in the 12th week of therapy. Reduction in tumor size before surgery,

reduction in intraoperative blood loss and an increase in prospective hematocrit are the benefits. It includes abdominal, laparoscopic, or hysteroscopic myomectomy for patients who want to preserve fertility.

- u hysterectomy (with preservation of the ovaries, if possible), which is the definitive treatment for symptomatic women who have completed childbearing.

Nursing diagnoses

u Altered sexuality patterns u Anxiety u Ineffective individual coping u Knowledge deficit u Pain

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will communicate feelings about the situation.
- u The patient will be involved in planning her own care.
- u The patient will use available support systems, such as family and friends, to aid in coping.
- u The patient will express feelings about the condition and its effect on sexuality.

Nursing interventions

- u In a patient with severe anemia due to excessive bleeding, administer iron and blood transfusions as ordered.
- u Encourage the patient and her partner to verbalize their feelings about the disorder and its effect on their relationship. Offer emotional support.
- u Help the patient develop effective coping strategies. Refer her and her partner to a mental health professional for additional counseling, if necessary.

Patient teaching

- u Tell the patient to report any abnormal bleeding or pelvic pain immediately.
- u If a hysterectomy or oophorectomy is indicated, explain the effects of the operation on menstruation, menopause, and sexual activity to the patient.
- u Reassure the patient that she won't experience premature menopause if her ovaries are left intact.
- u If the patient must have a multiple myomectomy, make sure she understands that pregnancy is still possible. However, if a hysterotomy is performed, explain that a cesarean delivery may be necessary.

VULVOVAGINITIS

Vulvovaginitis is an inflammation of the vulva (vulvitis) and vagina (vaginitis) that may occur at any age and affects most females at some time. Because of the proximity of these two structures, inflammation of one usually precipitates inflammation of the other. The prognosis is good with treatment.

Causes

Common causes of vaginitis (with or without consequent vulvitis) include:

- u infection with *Trichomonas vaginalis*, a protozoan flagellate that is usually transmitted through intercourse
- u infection with *Candida albicans*, a fungus that requires glucose for growth (Incidence increases during the secretory phase of the menstrual cycle. Such infection occurs twice as often in pregnant females as in nonpregnant females. It also commonly affects users of oral contraceptives, diabetic patients, and patients receiving systemic therapy with broad-spectrum antibiotics.)
- u bacterial vaginosis (previously known by various names such as *Gardnerella vaginitis*, *Haemophilus vaginalis*, and nonspecific vaginitis), which is characterized by a decrease in lactobacilli with an increase in anaerobic bacteria
- u venereal infection with *Neisseria gonorrhoeae* (gonorrhea), a gram-negative diplococcus
- u viral infection with venereal warts (*Condylomata acuminata*) or herpes simplex virus type 2, usually transmitted by intercourse
- u vaginal mucosa atrophy in menopausal women due to decreasing estrogen levels, which predisposes these women to bacterial invasion.

Common causes of vulvitis include:

- u parasitic infection (*Phthirus pubis*, crab louse), traumatic injury, or poor personal hygiene
- u chemical irritations or allergic reactions to hygiene sprays, douches, detergents, clothing, or toilet paper
- u vulval atrophy in menopausal women due to decreasing estrogen levels
- u retention of a foreign body, such as a tampon.

Complications

Inflammation and edema may affect the perineum. Skin breakdown may lead to secondary infection.

Assessment findings

Signs and symptoms may vary according to the infecting organism.

In *trichomonal vaginitis*, the patient may have vaginal irritation and itching along with urinary symptoms, such as burning and frequency. Inspection may reveal a vaginal discharge that is thin, bubbly, green-tinged, and malodorous.

A patient with *candidal vaginitis* may report intense vaginal itching and a thick, white, cottage-cheese-like discharge. Red, edematous mucous membranes with white flecks may be seen on the vaginal wall.

In *bacterial vaginosis*, inspection may disclose a gray, foul, fishy-smelling discharge, although some patients may be asymptomatic.

Gonorrhea may produce no symptoms, or inspection may reveal a profuse, purulent discharge; the patient may complain of dysuria.

In *acute vulvitis*, the patient may complain of vulvar burning, pruritus, severe dysuria, and dyspareunia. Inspection may reveal vulvar edema and erythema.

In *herpesvirus infection*, you may note ulceration or vesicle formation on the perineum during the active phase; in chronic infection, severe edema that may involve the entire perineum.

Diagnostic tests

Diagnosis of vaginitis requires identification of the infectious organism during microscopic examination of vaginal exudate on a wet slide preparation (vaginal exudate applied to the slide is moistened by a drop of normal saline solution and then a drop of potassium solution).

In trichomonal infections, the presence of motile, flagellated trichomonads confirms the diagnosis.

In monilial vaginitis, 10% potassium hydroxide is added to the slide; diagnosis requires identification of *C. albicans* fungus.

In bacterial vaginosis, saline wet mount shows the presence of clue cells (epithelial cells with bacteria adherent to the cell wall), giving it a stippled appearance.

Gonorrhea requires a culture of vaginal exudate to confirm the diagnosis.

Diagnosis of vulvitis or a suspected sexually transmitted disease may require a complete blood count, urinalysis, cytology screening, biopsy of chronic lesions to rule out cancer, and culture of exudate from acute lesions.

Treatment

Common therapeutic measures in vulvovaginitis include:

- u metronidazole given orally for the patient with trichomonal vaginitis and all sexual partners (if possible) because recurrence often results from reinfection by an infected, asymptomatic male
- u topical miconazole 2% or clotrimazole 1% for candidal infection
- u metronidazole for bacterial vaginosis
- u systemic antibiotics for the patient with gonorrhea and all sexual partners
- u doxycycline or erythromycin (for a concurrent chlamydial infection).

Cold compresses or cool sitz baths may relieve pruritus in acute vulvitis; severe inflammation may require warm compresses. Other therapy includes avoiding drying soaps, wearing loose clothing to promote air circulation, and applying topical corticosteroids to reduce inflammation.

Chronic vulvitis may respond to topical hydrocortisone or antipruritics and good hygiene (especially in elderly or incontinent patients). Topical estrogen ointments may be used to treat atrophic vulvovaginitis. There is no cure for herpesvirus infections; however, oral and topical acyclovir decreases the duration and symptoms of active lesions.

Local treatment of genital warts usually consists of application of trichloroacetic acid.

Nursing diagnoses

- u Altered sexuality patterns
- u Body image disturbance
- u Ineffective individual coping
- u Knowledge deficit
- u Pain
- u Risk for impaired skin integrity
- u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will remain free from signs of infection.
- u The patient will express concerns about self-concept, self-esteem, and body image.
- u The patient and spouse or partner will use available counseling or support group.

Nursing interventions

- u Encourage the patient to express her feelings and help her to develop effective coping strategies.
- u Provide comfort measures, such as cool or warm compresses, to alleviate pain, burning, and pruritus.
- u Use meticulous hand-washing technique. If necessary, use wound and skin precautions.
- u Report cases of sexually transmitted diseases to the public health authorities.

Patient teaching

- u Teach the patient about the correlation between sexual contact and the spread of vaginal infections. Provide information about the use of condoms to prevent or decrease the spread of sexually transmitted infections. Advise her to notify sexual partners of the need for treatment.
- u Advise the patient to abstain from sexual intercourse until the infection resolves.
- u Instruct her to use the entire medication prescription as ordered, even if symptoms subside.
- u Teach the patient how to insert vaginal ointments and suppositories. Tell her to remain prone for at least 30 minutes after insertion to promote absorption. Suggest that she wear a pad to prevent staining her underclothing.
- u Emphasize the need for meticulous hand washing before and after drug administration. Advise her that scratching can cause skin breakdown and secondary infections.
- u Encourage good hygiene. Advise the patient with a history of recurrent vulvovaginitis to wear all-cotton underpants. Tell her to avoid wearing tight-fitting pants and pantyhose.
- u Warn the patient on metronidazole therapy to abstain from alcoholic beverages because alcohol may provoke a disulfiram-type reaction. Also tell the patient that this drug may turn the urine dark brown.

Disorders of pregnancy

Many obstetric disorders—including spontaneous abortion, ectopic pregnancy, pregnancy-induced hypertension, placenta previa, abruptio placentae, and premature labor—require emergency care. These disorders and others, such as premature rupture of the membranes and puerperal infection, can threaten the life of the mother, the fetus, or both.

ABORTION

In spontaneous abortion (miscarriage) or induced (therapeutic) abortion, the products of conception are expelled from the uterus before fetal viability (fetal weight of less than 17½ oz [about 500 g] and gestation of less than 20 weeks). Up to 15% of all pregnancies and about 30% of first pregnancies end in miscarriage. At least 75% of miscarriages occur during the first trimester. The incidence of legal induced abortions is increasing in the United States. (See [Types of spontaneous abortion.](#))

Causes

Spontaneous abortion may result from fetal, placental, or maternal factors.

- u *Fetal factors* usually cause such abortions between 9 and 12 weeks of gestation and include defective embryologic development due to abnormal chromosome division (most common cause of fetal death), faulty implantation of fertilized ovum, and failure of the endometrium to accept the fertilized ovum.
- u *Placental factors* usually cause abortion around the 14th week of gestation when the placenta takes over the hormone production necessary to maintain the pregnancy. Factors include premature separation of the normally implanted placenta, abnormal placental implantation, and abnormal platelet function.
- u *Maternal factors* usually cause abortion between 11 and 19 weeks of gestation and include maternal infection, severe malnutrition, and abnormalities of the reproductive organs.

Other maternal factors include endocrine problems, such as thyroid gland dysfunction or lowered estriol secretion; trauma, including any type of surgery that necessitates manipulation of the pelvic organs; blood group incompatibility and Rh isoimmunization (still under investigation as a possible cause); and recreational drug use and environmental toxins.

Types of spontaneous abortion

Depending on clinical findings, a spontaneous abortion (miscarriage) may be threatened or inevitable, incomplete or complete, or missed, habitual, or septic. Here is how the seven types compare.

Threatened abortion

Bloody vaginal discharge occurs during the first half of pregnancy. About 20% of pregnant women have vaginal spotting or actual bleeding early in pregnancy; of these, about 50% abort.

Inevitable abortion

The membranes rupture and the cervix dilates. As labor continues, the uterus expels the products of conception.

Incomplete abortion

The uterus retains part or all of the placenta. Before the 10th week of gestation, the fetus and placenta usually are expelled together; after the 10th week, they're expelled separately. Because part of the placenta may adhere to the uterine wall, bleeding continues. Hemorrhage is possible because the uterus doesn't contract and seal the large vessels that fed the placenta.

Complete abortion

The uterus passes all the products of conception. Minimal bleeding usually accompanies complete abortion because the uterus contracts and compresses the maternal blood vessels that fed the placenta.

Missed abortion

The uterus retains the products of conception for 2 months or more after the death of the fetus. Uterine growth ceases; uterine size may even seem to decrease. Prolonged retention of the dead products of conception may cause coagulation defects such as disseminated intravascular coagulation.

Habitual abortion

Spontaneous loss of three or more consecutive pregnancies constitutes habitual abortion.

Septic abortion

Infection accompanies abortion. This may occur with spontaneous abortion but usually results from an illegal abortion or from the presence of an intrauterine device.

Therapeutic abortion is performed to preserve the mother's mental or physical health in cases of rape, unplanned pregnancy, or medical conditions, such as cardiac dysfunction or fetal abnormality.

Complications

Possible complications of abortion may include infections (if the products of conception aren't completely expelled), hemorrhage and anemia (if the bleeding is excessive and not controlled), and coagulation defects, such as disseminated intravascular coagulation (if the products of conception are retained for a long period).

Assessment findings

A patient who has experienced a spontaneous abortion may report a pink discharge for several days or a scant brown discharge for several weeks before onset of cramps and increased vaginal bleeding. She may describe cramps that appear for a few hours, intensify, and occur frequently.

If the patient has expelled the entire contents of the uterus, the cramps and bleeding may subside. However, if any contents remain, cramps and bleeding continue.

Diagnostic tests

Human chorionic gonadotropin (HCG) in the blood or urine confirms pregnancy; decreased HCG levels suggest spontaneous abortion. Cytologic analysis indicates evidence of products of conception. Laboratory tests reflect decreased hematocrit and hemoglobin levels due to blood loss. Ultrasound examination confirms the presence or absence of fetal heart tones or an empty amniotic sac. The newer vaginal probe technique enables earlier visualization of the gestational sac. Differential diagnosis is done to distinguish spontaneous abortion from cervicitis, ectopic pregnancy, gestational thromboplastic disease, and malignancy.

Treatment

An accurate evaluation of uterine contents is necessary before planning treatment.

The progression of spontaneous abortion can't be prevented, except in those cases caused by an incompetent cervix. Hospitalization is necessary to control severe hemorrhage. Severe bleeding requires transfusion with packed red blood cells or whole blood. Initially, I.V. administration of oxytocin stimulates uterine contractions. If remnants remain in the uterus, dilatation and curettage or dilatation and evacuation (D&E) should be performed.

D&E is also used in first-trimester induced abortions. In second-trimester induced abortions, an injection of hypertonic saline solution or of prostaglandin into the amniotic sac or insertion of a prostaglandin vaginal suppository induces labor and expulsion of uterine contents.

After a spontaneous or induced abortion, an Rh-negative female with a negative indirect Coombs' test should receive Rh ₀(D) immune globulin (RhoGAM) to prevent future Rh isoimmunization.

In a habitual aborter, spontaneous abortion can result from an incompetent cervix. Treatment involves surgical reinforcement of the cervix (cerclage) about 14 to 16 weeks after the last menstrual period. A few weeks before the estimated delivery date, the sutures are removed and the patient waits for the onset of labor. An alternative procedure, especially for the woman who wants to have more children, is to leave the sutures in place and to deliver the infant by cesarean section.

Nursing diagnoses

▫ Anxiety ▫ Dysfunctional grieving ▫ Ineffective family coping ▫ Ineffective individual coping ▫ Knowledge deficit ▫ Risk for infection

Key outcomes

▫ The patient will remain free from signs and symptoms of infection.
▫ The patient will communicate feelings about the current situation.

- u The patient will be involved in planning her own care.
- u The patient will express feelings of having greater control over the current situation.
- u The patient will use available support systems, such as family and friends, to aid in coping.

Nursing interventions

Before possible spontaneous abortion:

- u Do *not* allow bathroom privileges because the patient may expel uterine contents without knowing it. After she uses the bedpan, inspect the contents carefully for intrauterine material.

After spontaneous or elective abortion:

- u Note the amount, color, and odor of vaginal bleeding. Save all pads the patient uses for evaluation.
- u Administer analgesics and oxytocin as ordered.
- u Check the patient's blood type and administer RhoGAM as ordered.
- u Provide good perineal care.
- u Monitor vital signs every 4 hours for 24 hours.
- u Monitor urine output.

After spontaneous abortion:

- u Provide emotional support and counseling during the grieving process. Encourage the patient and her partner to express their feelings. Some couples may want to talk to a member of the clergy or, depending on their religion, may wish to have the fetus baptized.
- u Help the patient to develop effective coping strategies.

After elective abortion:

- u Encourage the patient to verbalize her feelings. Remember, she may feel ambivalent about the procedure; intellectual and emotional acceptance of abortion aren't the same. Refer her for counseling, if necessary.

Patient teaching

- u Explain all procedures thoroughly.
- u Tell the patient to expect vaginal bleeding or spotting and to report immediately any bleeding that lasts longer than 8 to 10 days or excessive, bright red blood.
- u Advise the patient to watch for signs of infection, such as a temperature higher than 100° F (37.8° C) and foul-smelling vaginal discharge.
- u Encourage the gradual increase of daily activities to include whatever tasks the patient feels comfortable doing if these activities don't increase vaginal bleeding or cause fatigue. Most patients return to work within 1 to 4 weeks.
- u Urge 1 to 2 weeks of abstinence from intercourse and encourage the use of a contraceptive when the patient resumes intercourse.
- u Instruct the patient to avoid using tampons for 1 to 2 weeks.
- u Tell the patient to see her doctor in 2 to 4 weeks for a follow-up examination. (See [Preventing spontaneous abortion.](#))

For elective abortion:

- u Be sure to inform the patient of all the available alternatives. She needs to know what the procedure involves, what the risks are, and what to expect during and after the procedure, both emotionally and physically. Be sure to ascertain whether the patient is comfortable with her decision to have an elective abortion. Encourage her to verbalize her thoughts when the procedure is performed and at a follow-up visit, usually 2 weeks later. If you identify an inappropriate coping response, refer the patient for professional counseling.

PREVENTION

Preventing spontaneous abortion

To minimize risk of future spontaneous abortion, emphasize to the pregnant woman the importance of good nutrition and the need to avoid alcohol, cigarettes, and drugs. The couple should also wait for two to three normal menstrual cycles after spontaneous abortion before attempting conception.

If there is a history of spontaneous abortion, suggest that she and her partner have a thorough examination. This may include premenstrual endometrial biopsy, hormone assessment (estrogen, progesterone, and thyroid, follicle-stimulating, and luteinizing hormones), and hysterosalpingography and laparoscopy to detect anatomic abnormalities. Genetic counseling may also be indicated.

- u To reduce the risks associated with repeated elective abortion, provide the patient with contraceptive information.

ABRUPTIO PLACENTAE

Abruptio placentae—also called placental abruption—occurs when the placenta separates from the uterine wall prematurely, usually after the 20th week of gestation, producing hemorrhage. This disorder may be classified according to the degree of placental separation and the severity of maternal and fetal symptoms. (See [Degrees of placental separation in abruptio placentae.](#))

Abruptio placentae is most common in multigravidas—usually in women over age 35—and is a common cause of bleeding during the second half of pregnancy. A firm diagnosis when there is heavy maternal bleeding generally necessitates termination of the pregnancy. The fetal prognosis depends on the gestational age and amount of blood lost. The maternal prognosis is good if hemorrhage can be controlled.

Causes and pathophysiology

The cause of abruptio placentae is unknown. Predisposing factors include traumatic injury (such as a direct blow to the uterus), placental site bleeding from a needle puncture during amniocentesis, chronic or pregnancy-induced hypertension (which raises pressure on the maternal side of the placenta), multiparity, short umbilical cord, dietary deficiency, smoking, advanced maternal age, and pressure on the vena cava from an enlarged uterus.

Degrees of placental separation in abruptio placentae

Placental abruption is classified according to the degree of placental separation from the uterine wall and the extent of hemorrhage.

Mild separation

Internal bleeding between the placenta and uterine wall characterizes mild separation.

Moderate separation

In moderate separation, external hemorrhage occurs through the vagina.

Severe separation

External hemorrhage is also characteristic in severe separation.

The spontaneous rupture of blood vessels at the placental bed may be due to lack of resiliency or to abnormal changes in the uterine vasculature. The condition may be complicated by hypertension or by an enlarged uterus that can't contract sufficiently to seal off the torn vessels. Consequently, bleeding continues unchecked, possibly shearing off the placenta partially or completely.

Complications

Besides hemorrhage and shock, possible complications of abruptio placentae include renal failure, disseminated intravascular coagulation (DIC), and maternal and fetal death.

Assessment findings

Abruptio placentae produces a wide range of clinical effects, depending on the extent of placental separation and the amount of blood lost from maternal circulation.

A patient with *mild abruptio placentae* (marginal separation) may report mild to moderate vaginal bleeding, vague lower abdominal discomfort, and mild to moderate abdominal tenderness. Fetal monitoring may indicate uterine irritability. Auscultation reveals strong and regular fetal heart tones.

A patient with *moderate abruptio placentae* (about 50% placental separation) may report continuous abdominal pain and moderate dark red vaginal bleeding. Onset of symptoms may be gradual or abrupt.

Vital signs may indicate impending shock. Palpation reveals a tender uterus that remains firm between contractions. Fetal monitoring may reveal barely audible or irregular and bradycardic fetal heart tones. Labor usually starts within 2 hours and often proceeds rapidly.

A patient with *severe abruptio placentae* (70% placental separation) will report abrupt onset of agonizing, unremitting uterine pain (described as tearing or knifelike) and moderate vaginal bleeding.

Vital signs indicate rapidly progressive shock. Fetal monitoring indicates an absence of fetal heart tones.

Palpation reveals a tender uterus with boardlike rigidity. Uterine size may increase in severe concealed abruptions.

ASSESSMENT TIP Draw a line at the level of the fundus and check it every 30 minutes. If the level of the fundus increases, suspect abruptio placentae.

Diagnostic tests

Pelvic examination under double setup (preparations for an emergency cesarean) and ultrasonography are performed to rule out placenta previa. Decreased hemoglobin levels and platelet counts support the diagnosis. Periodic assays for fibrin split products aid in monitoring the progression of abruptio placentae and in detecting DIC. Differential diagnosis excludes placenta previa, ovarian cysts, appendicitis, and degeneration of leiomyomas.

Treatment

Medical management of abruptio placentae is intended to assess, control, and restore the amount of blood lost; to deliver a viable infant; and to prevent coagulation disorders.

Immediate measures for abruptio placentae include starting an I.V. infusion (by large-bore catheter) of appropriate fluids (lactated Ringer's solution) to combat hypovolemia, inserting a central venous pressure line and an indwelling urinary catheter to monitor fluid status, drawing blood for hemoglobin and hematocrit determination and coagulation studies and for typing and cross matching, starting external electronic fetal monitoring, and monitoring maternal vital signs and vaginal bleeding.

After determining the severity of placental abruption and appropriate fluid and blood replacement, prompt delivery by cesarean section is necessary if the fetus is in distress. If the fetus isn't in distress, monitoring continues; delivery is usually performed at the first sign of fetal distress. (If placental separation is severe with no signs of fetal life, vaginal delivery may be performed unless uncontrolled hemorrhage or other complications contraindicate it.)

Because of possible fetal blood loss through the placenta, a pediatric team should be ready at delivery to assess and treat the neonate for shock, blood loss, and hypoxia.

Complications of abruptio placentae require appropriate treatment. With a complication, such as DIC, for example, the patient needs immediate intervention with heparin, platelets, and whole blood, as ordered, to prevent exsanguination.

Nursing diagnoses

u Altered tissue perfusion u Anxiety u Dysfunctional grieving u Fear u Fluid volume deficit u Ineffective family coping u Ineffective individual coping u Knowledge deficit u Pain

Key outcomes

- u The patient's vital signs will remain stable.
- u The patient's fluid volume will remain within normal parameters.
- u The patient will express feelings of comfort.
- u The patient will communicate feelings about the situation.
- u The patient will use available support systems, such as family and friends, to aid in coping.

Nursing interventions

- u Monitor maternal blood pressure, pulse rate, respirations, central venous pressure, intake and output, and amount of vaginal bleeding every 10 to 15 minutes.
- u Monitor fetal heart rate electronically.
- u If vaginal delivery is elected, provide emotional support during labor. Because of the neonate's prematurity, the mother may not receive analgesics during labor and may experience intense pain. Reassure the patient of her progress through labor and keep her informed of the fetus's condition.
- u Encourage the patient and family members to verbalize their feelings. Help them to develop effective coping strategies. Refer them for counseling, if necessary.

Patient teaching

- u Teach the patient to identify and report signs of placental abruption, such as bleeding and cramping.
- u Explain all procedures and treatments to allay anxiety.
- u Prepare the patient and family members for the possibility of an emergency cesarean section, the delivery of a premature infant, and the changes to expect in the postpartum period. Offer emotional support and an honest assessment of the situation.
- u Tactfully discuss the possibility of neonatal death. Tell the mother that the neonate's survival depends primarily on gestational age, the amount of blood lost, and associated hypertensive disorders. Assure her that frequent monitoring and prompt management greatly reduce the risk of death.

ECTOPIC PREGNANCY

Ectopic pregnancy is the implantation of a fertilized ovum outside the uterine cavity. It most commonly occurs in the fallopian tube, but other sites are possible. (See [Implantation sites of ectopic pregnancy.](#))

In whites, ectopic pregnancy occurs in about 1 in 200 pregnancies; in nonwhites, in about 1 in 120. The prognosis for the patient is good with prompt diagnosis, appropriate surgical intervention, and control of bleeding; rarely, in cases of abdominal implantation, the fetus may survive to term. Usually, only 1 in 3 women who experience an ectopic pregnancy give birth to a live neonate in a subsequent pregnancy.

Causes

Conditions that prevent or retard the passage of the fertilized ovum through the fallopian tube and into the uterine cavity include:

- u *endosalpingitis*, an inflammatory reaction that causes folds of the tubal mucosa to agglutinate, narrowing the tube
- u *diverticula*, the formation of blind pouches that cause tubal abnormalities
- u *tumors* pressing against the tube
- u *previous surgery* (tubal ligation or resection, or adhesions from previous abdominal or pelvic surgery)
- u *transmigration of the ovum* (from one ovary to the opposite tube), resulting in delayed implantation.

Ectopic pregnancy may also result from congenital defects in the reproductive tract or ectopic endometrial implants in the tubal mucosa. The increased prevalence of

sexually transmitted tubal infection may also be a factor as may the use of an intrauterine device, which causes irritation of the cellular lining of the uterus and the fallopian tubes.

Complications

Rupture of the tube causes life-threatening complications, including hemorrhage, shock, and peritonitis. Infertility results if the uterus or both fallopian tubes or both ovaries are removed.

Assessment findings

Ectopic pregnancy sometimes produces symptoms of normal pregnancy or no symptoms other than mild abdominal pain (the latter is especially likely in abdominal pregnancy), making diagnosis difficult.

Typically, the patient reports amenorrhea or abnormal menses (after fallopian tube implantation), followed by slight vaginal bleeding and unilateral pelvic pain over the mass.

If the tube ruptures, the patient may complain of sharp lower abdominal pain, possibly radiating to the shoulders and neck. She may indicate that this pain is often precipitated by activities that increase abdominal pressure such as a bowel movement.

During a pelvic examination, the patient may report extreme pain when the cervix is moved and the adnexa is palpated. The uterus feels boggy and is tender.

Diagnostic tests

Serum pregnancy (human chorionic gonadotropin [HCG]) test result shows an abnormally low level of HCG and, when repeated in 48 hours, the level remains lower than the levels found in a normal intrauterine pregnancy.

Real-time ultrasonography determines intrauterine pregnancy or ovarian cyst (performed if serum pregnancy test results are positive).

Culdocentesis (aspiration of fluid from the vaginal cul-de-sac) detects free blood in the peritoneum (performed if ultrasonography detects absence of a gestational sac in the uterus).

Laparoscopy may reveal pregnancy outside the uterus (performed if culdocentesis is positive).

Differential diagnosis is used to rule out intrauterine pregnancy, ovarian cyst or tumor, pelvic inflammatory disease (PID), appendicitis, and recent spontaneous abortion.

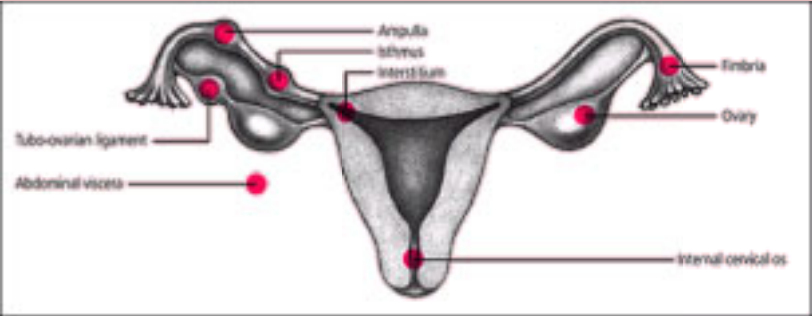

Treatment

If culdocentesis shows blood in the peritoneum, laparotomy and salpingectomy are indicated, possibly preceded by laparoscopy to remove the affected fallopian tube and control bleeding. Patients who wish to have children can undergo microsurgical repair of the fallopian tube. The ovary is saved, if possible; ovarian pregnancy requires oophorectomy. Nonsurgical management of ectopic pregnancy involves the use of methotrexate, a chemotherapeutic agent, administered orally, I.M., or by local infiltration to destroy remaining trophoblastic tissue and avoid the need for laparotomy.

Interstitial pregnancy may require hysterectomy; abdominal pregnancy requires a laparotomy to remove the fetus, except in rare cases, when the fetus survives to term or calcifies undetected in the abdominal cavity.

Implantation sites of ectopic pregnancy

In about 95% of patients with ectopic pregnancy, the ovum implants in part of the fallopian tube: the fimbria, ampulla, or isthmus. Other possible abnormal sites of implantation include the interstitium, tubo-ovarian ligament, ovary, abdominal viscera, and internal cervical os.

Supportive treatment includes transfusion with whole blood or packed red blood cells to replace excessive blood loss, administration of broad-spectrum I.V. antibiotics for sepsis, administration of supplemental iron (given orally or I.M.), and institution of a high-protein diet.

Nursing diagnoses

- u Anxiety
- u Dysfunctional grieving
- u Fear
- u Fluid volume deficit
- u Ineffective individual coping
- u Knowledge deficit

Key outcomes

- u The patient's vital signs will remain stable.
- u The patient will maintain adequate fluid volume.
- u The patient will express feelings about the current situation.
- u The patient will be involved in planning her own care.
- u The patient will use available support systems, such as family and friends, to aid in coping.

Nursing interventions

- u Assess vital signs and monitor vaginal bleeding. Prepare the patient with excessive blood loss for emergency surgery. Administer blood transfusions (for replacement) as ordered and provide emotional support.
- u Record the location and character of the pain and administer analgesics as ordered.
- u Check the amount, color, and odor of vaginal bleeding.
- u Monitor vital signs and fluid intake and output for signs of hypovolemia and impending shock.
- u Determine if the patient is Rh-negative. If she is, administer Rh₀(D) immune globulin (RhoGAM) as ordered. Ask the patient the date of her last menstrual period and have her describe the character of this period.
- u Provide a quiet, relaxing environment and encourage the patient and her partner to express their feelings of fear, loss, and grief. Help the patient to develop effective coping strategies. Refer her to a mental health professional for additional counseling, if necessary.

Patient teaching

- u Teach the patient about the anatomic structures and reproductive processes involved in this disorder. Explain all procedures and treatment options. Prepare her for surgery and discuss what to expect postoperatively.
- u To prevent recurrent ectopic pregnancy, advise prompt treatment of pelvic infections to prevent diseases of the fallopian tube. Inform patients who have undergone surgery involving the fallopian tubes or those with confirmed PID that they are at increased risk for another ectopic pregnancy.

GESTATIONAL TROPHOBLASTIC DISEASE

Depending on histopathologic changes that occur in the trophoblast cells of the chorionic villi, gestational trophoblastic disease takes one of three forms. The first is *hydatidiform mole*, a nonmalignant neoplasm that forms on the chorion (the outer layer of the membrane containing amniotic fluid). The second form, commonly called *invasive mole* (chorioadenoma destruens), is a self-limiting, malignant tumor that occurs when trophoblastic tissue continues to grow and locally invades the uterine myometrium and pelvic blood supply. The third category is *choriocarcinoma*, a serious, rapidly developing, but rare, carcinoma. Neoplastic trophoblasts proliferate without cystic villi and may metastasize profusely throughout the body.

Gestational trophoblastic disease is reported to occur in about 1 in every 2,000 pregnancies. Recent research indicates that the incidence would be much higher if all cases of the disorder were identified. Some cases aren't recognized because the pregnancy is aborted early and the products of conception aren't available for analysis. The incidence is increased in women from low socioeconomic groups, older women, and multiparous women. The incidence is highest in Asian women, especially those from Southeast Asia.

With prompt diagnosis and appropriate treatment, the prognosis is usually excellent for patients with hydatidiform or invasive mole; about 10% of patients with hydatidiform mole develop choriocarcinoma. Recurrence is possible in about 2% of patients.

Causes

The cause of hydatidiform mole is unknown. Several unsubstantiated theories relate gestational trophoblastic disease to a nutritional deficit, specifically an insufficient intake of protein and folic acid; chromosomal abnormalities; or hormonal imbalances. About half the patients with choriocarcinoma have had a preceding molar pregnancy. In the remaining half, the disease is usually preceded by a spontaneous or induced abortion, ectopic pregnancy, or normal pregnancy.

Complications

Possible complications of hydatidiform and invasive moles include anemia, infection, spontaneous abortion, uterine rupture, and hemorrhage.

Complications of invasive mole and choriocarcinoma include metastasis to all body structures. In invasive mole, metastasis occurs occasionally to the vagina and lungs. (This lesion accounts for the majority of women who have persistently high human chorionic gonadotropin [HCG] levels after the evacuation of a molar pregnancy.)

Choriocarcinoma disseminates hematogenously, particularly to the lungs, brain, liver, kidneys, and GI tract.

Assessment findings

A patient with hydatidiform mole may report vaginal bleeding, ranging from brownish red spotting to bright red hemorrhage. She may report passing tissue that resembles grape clusters. Her history may also include lower abdominal cramps, such as those that accompany spontaneous abortion, hyperemesis, and signs and symptoms of preeclampsia.

On inspection, a uterus that is exceptionally large for the patient's gestational date is detected. On pelvic examination, you may discover grapelike vesicles in the vagina. Palpation may reveal ovarian enlargement due to theca-lutein cysts. Auscultation of the uterus may reveal the absence of fetal heart tones normally noted during a previous visit.

A patient with choriocarcinoma typically reports vaginal bleeding. If the disease has metastasized, she may also report hemoptysis, cough, dyspnea, headache, dizzy spells, weakness, paralysis, and rectal bleeding.

Occasionally, a patient with choriocarcinoma may exhibit an acute abdomen due to rupture of the uterus, liver, or theca-lutein cyst. On inspection, the uterus may be enlarged, with blood coming through the os. A tumor may be visible in the vagina.

Diagnostic tests

Radioimmunoassay of HCG levels, performed frequently, can allow early and accurate diagnosis. HCG levels that are extremely elevated for early pregnancy indicate gestational trophoblastic disease.

Histologic examination of possible hydatid vesicles is used to confirm the diagnosis.

Ultrasonography performed after the third month shows grapelike clusters rather than a fetus.

Amniography, a procedure that introduces a water-soluble dye into the uterus, may reveal the absence of a fetus (performed only when the diagnosis is in question).

Doppler ultrasonography demonstrates the absence of fetal heart tones.

Hemoglobin level and hematocrit, red blood cell count, prothrombin time, partial thromboplastin time, fibrinogen levels, and hepatic and renal function findings are abnormal.

White blood cell count and erythrocyte sedimentation rate are increased.

Chest X-rays, computed tomography scanning, and magnetic resonance imaging may be used to identify choriocarcinoma metastasis.

Lumbar puncture may reveal early cerebral metastasis if HCG is in the cerebrospinal fluid.

Differential diagnosis is used to rule out normal pregnancy, threatened abortion, uterine leiomyomas, multiple gestation, and incorrect gestational date.

Treatment

Gestational trophoblastic disease necessitates uterine evacuation by dilatation and curettage, abdominal hysterectomy, or instrument or suction curettage, depending on uterine size. I.V. oxytocin may be used to promote uterine contractions.

Postoperative treatment varies, depending on the amount of blood lost and complications. If no complications develop, hospitalization is usually brief and normal activities can be resumed quickly, as tolerated.

Because of the possibility of choriocarcinoma development following hydatidiform mole, scrupulous follow-up care is essential. Such care includes monitoring HCG levels once weekly until titers are negative for 3 consecutive weeks; then once monthly for 6 months; then every 2 months for 6 months. It also includes chest X-rays to check for lung metastasis once monthly until HCG titers are negative, then once every 2 months for 1 year.

Another pregnancy should be postponed until at least 1 year after all titers and X-ray findings are negative. An oral contraceptive is indicated to prevent pregnancy.

Prophylactic chemotherapy with either methotrexate or actinomycin D after evacuation of the uterus has been successful in preventing malignant gestational trophoblastic disease. Chemotherapy with combination therapy and irradiation are used for metastatic choriocarcinoma.

Nursing diagnoses

- u Anxiety
- u Dysfunctional grieving
- u Ineffective family coping: Disabling
- u Ineffective individual coping
- u Knowledge deficit
- u Risk for infection

Key outcomes

- u The patient will remain free from signs and symptoms of infection.
- u The patient will communicate feelings about the situation.
- u The patient will be involved in planning her care.
- u The patient will express feelings of having greater control over the current situation.
- u The patient will use available support systems, such as friends and family, to aid in coping.

Nursing interventions

- u Preoperatively, observe for signs of complications, such as hemorrhage and uterine infection, and vaginal passage of hydatid vesicles. Save any expelled tissue for laboratory analysis.
- u Postoperatively monitor vital signs, fluid intake and output, and for signs of hemorrhage.
- u Encourage the patient and family members to express their feelings about the disorder. Offer emotional support and help them through the grieving process for their lost infant.
- u Help the patient and family members to develop effective coping strategies. Refer them to a mental health professional for additional counseling, if needed.

Patient teaching

- u Stress the need for regular monitoring (HCG levels and chest X-rays) to detect any malignant changes.
- u Instruct the patient to report promptly any new symptoms (for example, hemoptysis, cough, suspected pregnancy, nausea, vomiting, and vaginal bleeding).
- u Explain to the patient that she must use contraceptives to prevent pregnancy for at least 1 year after HCG levels return to normal and her body reestablishes regular ovulation and menstrual cycles.

HYPEREMESIS GRAVIDARUM

Unlike the transient nausea and vomiting normally experienced until about the 12th week of pregnancy, hyperemesis gravidarum is severe and unremitting nausea and vomiting that persists after the first trimester. It usually occurs with the first pregnancy and commonly affects pregnant women with conditions that produce high levels of human chorionic gonadotropin, such as hydatidiform mole or multiple pregnancy.

This disorder occurs among blacks in about 7 in 1,000 pregnancies and among whites in about 16 in 1,000 pregnancies. The prognosis is good.

Causes

The specific cause of hyperemesis gravidarum is unknown. Possible causes include pancreatitis (elevated serum amylase levels are common), biliary tract disease, decreased secretion of free hydrochloric acid in the stomach, decreased gastric motility, drug toxicity, inflammatory obstructive bowel disease, and vitamin deficiency (especially of B₆). In some patients, this disorder may be related to psychological factors.

Complications

If untreated, hyperemesis gravidarum produces substantial weight loss; starvation, with ketosis and acetonuria; dehydration, with subsequent fluid and electrolyte imbalance (hypokalemia); and acid-base disturbances (acidosis and alkalosis). Retinal, neurologic, and renal damage may also occur.

Assessment findings

The patient typically complains of unremitting nausea and vomiting, the cardinal symptoms of hyperemesis gravidarum. The vomitus initially contains undigested food, mucus, and small amounts of bile; later, it contains only bile and mucus; and finally, blood and material that resembles coffee grounds. The patient may report substantial weight loss and eventual emaciation caused by persistent vomiting, thirst, hiccups, oliguria, vertigo, and headache.

Inspection may reveal pale, dry, waxy, and possibly jaundiced skin, with decreased skin turgor; a dry and coated tongue; subnormal or elevated temperature; rapid pulse; and a fetid, fruity breath odor from acidosis. The patient may appear confused and delirious. Lassitude, stupor and, possibly, coma may occur.

Diagnostic tests

Diagnosis is used to rule out other disorders, such as gastroenteritis, cholecystitis, and peptic ulcer, which produce similar clinical effects. Differential diagnosis also rules out hydatidiform gestation, hepatitis, inner ear infection, food poisoning, emotional problems, and eating disorders.

The following test results support a diagnosis of hyperemesis gravidarum:

- u Serum analysis shows decreased protein, chloride, sodium, and potassium levels and increased blood urea nitrogen levels.
- u Other laboratory tests reveal ketonuria, slight proteinuria, elevated hemoglobin levels, and an elevated white blood cell count.

Treatment

The patient with hyperemesis gravidarum may require hospitalization to correct electrolyte imbalance and prevent starvation. I.V. infusions are used to maintain nutrition until she can tolerate oral feedings. She progresses slowly to a clear liquid diet, then a full liquid diet, and finally, small, frequent meals of high-protein solid foods. A midnight snack helps stabilize blood glucose levels.

Parenteral vitamin supplements and potassium replacements help correct deficiencies.

When persistent vomiting jeopardizes health, antiemetic medications are administered. Currently, only meclizine and diphenhydramine are known to have a low risk for teratogenicity.

When vomiting stops and electrolyte balance has been restored, the pregnancy usually continues without recurrence of hyperemesis gravidarum. Most patients feel better as they begin to regain normal weight, but some continue to vomit throughout the pregnancy, requiring extended treatment. If appropriate, some patients may

benefit from consultations with clinical nurse specialists, psychologists, or psychiatrists.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered protection
- u Anxiety
- u Fluid volume deficit
- u Ineffective individual coping
- u Knowledge deficit

Key outcomes

- u The patient will maintain adequate fluid volume.
- u The patient will maintain adequate calorie intake and daily requirements.
- u The patient's intake will equal her output.
- u The patient will express feelings about current situation.
- u The patient will use available support systems, such as friends and family, to aid in coping.

Nursing interventions

- u Maintain I.V. fluids as ordered until the patient can tolerate oral feedings.
- u Monitor fluid intake and output, vital signs, weight, serum electrolyte levels, and urine for ketones.
- u Provide frequent mouth care.
- u Consult a dietitian to provide a diet high in dry, complex carbohydrates. Suggest decreased liquid intake during meals. Company and diversionary conversation at mealtime may be beneficial.
- u Provide reassurance and a calm, restful atmosphere. Encourage the patient to discuss her feelings about her pregnancy and the disorder.
- u Help the patient develop effective coping strategies. Refer her to a mental health professional for additional counseling, if necessary. Refer her to the social service department for help in caring for other children at home, if appropriate.

Patient teaching

- u Instruct the patient to remain upright for 45 minutes after eating to decrease reflux.
- u Suggest that the patient eat two or three dry crackers on awakening in the morning, before getting out of bed, to alleviate nausea.
- u Teach the patient protective measures to conserve energy and promote rest. Include relaxation techniques; fresh air and moderate exercise, if tolerated; and activities scheduled to prevent fatigue.

PLACENTA PREVIA

In this disorder, the placenta implants in the lower uterine segment, where it encroaches on the internal cervical os. Placenta previa, one of the most common causes of bleeding during the second half of pregnancy, occurs in about 1 in 200 pregnancies, more commonly in multigravidas than in primigravidas.

The placenta may cover all, part, or a fraction of the internal cervical os. (See [Three types of placenta previa.](#))

Among patients who develop placenta previa in the second trimester of pregnancy, less than 15% have a persistent previa at term. The elongation of the upper and lower uterine segments causes the placenta to be located higher on the uterine wall.

Generally, termination of pregnancy is necessary when placenta previa is diagnosed in the presence of heavy maternal bleeding. The maternal prognosis is good if hemorrhage can be controlled; the fetal prognosis depends on gestational age and the amount of blood lost.

Causes

The specific cause of placenta previa is unknown. Factors that may affect the site of the placenta's attachment to the uterine wall include:

- u defective vascularization of the decidua
- u multiple pregnancy (the placenta requires a larger surface for attachment)
- u previous uterine surgery
- u multiparity
- u advanced maternal age.

Complications

Possible complications of placenta previa include anemia, hemorrhage, disseminated intravascular coagulation, shock, renal damage, cerebral ischemia, and maternal or fetal death.

Assessment findings

Typically, a patient with placenta previa reports the onset of painless, bright red, vaginal bleeding after the 20th week of pregnancy. Such bleeding, beginning before the onset of labor, tends to be episodic; it starts without warning, stops spontaneously, and resumes later.

About 7% of all patients with placenta previa are asymptomatic. In these women, ultrasound examination reveals the disorder incidentally.

Palpation may reveal a soft, nontender uterus. Abdominal examination using Leopold's maneuvers reveals various malpresentations due to interference with the descent of the fetal head caused by the placenta's abnormal location. Minimal descent of the fetal presenting part may indicate placenta previa. The fetus remains active, however, with good heart tones audible on auscultation.

Diagnostic tests

Transvaginal ultrasound scanning is used to determine placental position.

Pelvic examination (under a double setup [preparations for an emergency cesarean] because of the likelihood of hemorrhage) performed immediately before delivery is used to confirm the diagnosis. In most cases, only the cervix is visualized.

Laboratory studies may reveal decreased maternal hemoglobin levels (due to blood loss).

Differential diagnosis excludes genital lacerations, excessive bloody show, abruptio placentae, and cervical lesions.

Three types of placenta previa

The degree of placenta previa depends largely on the extent of cervical dilation at the time of examination because the dilating cervix gradually uncovers the placenta, as shown below.

Marginal placenta previa

If the placenta covers just a fraction of the internal cervical os, your patient has marginal, or low-lying, placenta previa.

Partial placenta previa

Your patient has the partial, or incomplete, form of the disorder if the placenta caps a larger part of the internal os.

Total placenta previa

If the placenta covers all of the internal os, your patient has total, complete, or central placenta previa.

Treatment

Medical management of placenta previa is intended to assess, control, and restore blood loss; deliver a viable infant; and prevent coagulation disorders.

Immediate therapy includes starting an I.V. infusion using a large-bore catheter; drawing blood for hemoglobin and hematocrit levels and for typing and cross matching; initiating external electronic fetal monitoring; monitoring maternal blood pressure, pulse rate, and respirations; and assessing the amount of vaginal bleeding.

If the fetus is premature (following determination of the degree of placenta previa and necessary fluid and blood replacement), treatment consists of careful observation to allow the fetus more time to mature.

If clinical evaluation confirms complete placenta previa, the patient is usually hospitalized due to the increased risk of hemorrhage. As soon as the fetus is sufficiently mature, or in case of intervening severe hemorrhage, immediate delivery by cesarean section may be necessary.

Vaginal delivery is considered only when the bleeding is minimal and the placenta previa is marginal or when the labor is rapid.

Because of possible fetal blood loss through the placenta, a pediatric team should be on hand during such delivery to immediately assess and treat neonatal shock, blood loss, and hypoxia.

Nursing diagnoses

u Anxiety u Dysfunctional grieving u Fear u Fluid volume deficit u Ineffective family coping u Ineffective individual coping u Knowledge deficit u Pain u Risk for injury

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's vital signs will remain stable.
- u The patient's fluid volume will remain within normal parameters.
- u The patient will express feelings about current condition.
- u The patient will use available support systems, such as family and friends, to aid in coping.

Nursing interventions

- u If the patient with placenta previa shows active bleeding, continuously monitor her blood pressure, pulse rate, respirations, central venous pressure, intake and output, amount of vaginal bleeding, and the fetal heart rate. Electronic monitoring of fetal heart tones is recommended.
- u If the patient is Rh-negative, administer Rh_o(D) immune globulin (RhoGAM) after every bleeding episode.
- u Provide emotional support during labor. Because of the infant's prematurity, the patient may not be given analgesics, so labor pain may be intense. Reassure her of her progress throughout labor and keep her informed of the fetus's condition.
- u During the postpartum period, monitor the patient for signs of hemorrhage and shock caused by the uterus's diminished ability to contract.
- u Encourage the patient and family members to verbalize their feelings. Help them to develop effective coping strategies. Refer them for counseling, if necessary.

Patient teaching

- u Teach the asymptomatic patient to identify and report signs of placenta previa (bleeding, cramping) immediately.
- u Prepare the patient and family members for the possibility of an emergency cesarean section, the birth of a premature infant, and the physical and emotional changes of the postpartum period.
- u Tactfully discuss the possibility of neonatal death. Tell the mother that the infant's survival depends primarily on gestational age, the amount of blood lost, and associated hypertensive disorders. Assure her that frequent monitoring and prompt management greatly reduce the risk of death.

PREGNANCY-INDUCED HYPERTENSION

Pregnancy-induced hypertension is a potentially life-threatening disorder that usually develops after the 20th week of pregnancy. It most often occurs in nulliparous women and may be nonconvulsive or convulsive.

Preeclampsia, the nonconvulsive form of the disorder, is marked by the onset of hypertension after 20 weeks of gestation. It develops in about 7% of pregnancies and may be mild or severe. The incidence is significantly higher in low socioeconomic groups.

Eclampsia, the convulsive form, occurs between 24 weeks' gestation and the end of the first postpartum week. The incidence increases among women who are pregnant for the first time, have multiple fetuses, and have a history of vascular disease.

About 5% of women with preeclampsia develop eclampsia; of these, about 15% die of eclampsia or its complications. Fetal mortality is high because of the increased incidence of premature delivery

Pregnancy-induced hypertension and its complications are the current most common cause of maternal death in developed countries.

Causes

The cause of pregnancy-induced hypertension is unknown. Geographic, ethnic, racial, nutritional, immunologic, and familial factors may contribute to preexisting vascular disease, which, in turn, may contribute to its occurrence. Age is also a factor. Adolescents and primiparas over age 35 are at higher risk for preeclampsia.

Other theories include a long list of potential toxic sources, such as autolysis of placental infarcts, autointoxication, uremia, maternal sensitization to total proteins, and pyelonephritis.

Complications

Generalized arteriolar vasoconstriction is thought to produce decreased blood flow through the placenta and maternal organs. This can result in intrauterine growth retardation (or restriction), placental infarcts, and abruptio placentae. Hemolysis, elevated liver enzyme levels, and a low platelet count (HELLP syndrome) characterize severe eclampsia. A unique form of coagulopathy is also associated with this disorder.

Other possible complications include stillbirth of the neonate, seizures, coma, premature labor, renal failure, and hepatic damage in the mother.

Assessment findings

A patient with mild preeclampsia typically reports a sudden weight gain of more than 3 lb (1.4 kg) a week in the second trimester or more than 1 lb (0.5 kg) a week during the third trimester.

The patient's history reveals hypertension, as evidenced by elevated blood pressure readings: 140 mm Hg or more systolic, or an increase of 30 mm Hg or more above the patient's normal systolic pressure, measured on two occasions, 6 hours apart; and 90 mm Hg or more diastolic, or an increase of 15 mm Hg or more above the patient's normal diastolic pressure, measured on two occasions, 6 hours apart.

WARNING

**Emergency interventions**

When caring for a patient with pregnancy-induced hypertension, be prepared to perform these nursing interventions.

- u Observe for signs of fetal distress by closely monitoring the results of stress and nonstress tests.
- u Keep emergency resuscitative equipment and anticonvulsants available in case of seizures and cardiac or respiratory arrest. Carefully monitor the administration of magnesium sulfate. Signs of toxicity include absence of patellar reflexes, flushing, muscle flaccidity, decreased urine output, a significant drop in blood pressure (more than 15 mm Hg), and respiration less than 12 breaths/ minute. Keep calcium gluconate at the bedside to counteract the toxic effects of magnesium sulfate.
- u Prepare for emergency cesarean section, if indicated. Alert the anesthesiologist and pediatrician.
- u To protect the patient from injury, maintain seizure precautions. Don't leave an unstable patient unattended. Keep an airway open and oxygen available.

Inspection reveals generalized edema, especially of the face. Palpation may reveal pitting edema of the legs and feet. Deep tendon reflexes may indicate hyperreflexia.

As preeclampsia worsens, the patient may demonstrate oliguria (urine output of 400 ml/day or less), blurred vision caused by retinal arteriolar spasms, epigastric pain or heartburn, irritability, and emotional tension. She may complain of a severe frontal headache.

In severe preeclampsia, blood pressure readings increase to 160/110 mm Hg or higher on two occasions, 6 hours apart, during bed rest. Also, ophthalmoscopic examination may reveal vascular spasm, papilledema, retinal edema or detachment, and arteriovenous nicking or hemorrhage.

Preeclampsia can suddenly progress to eclampsia with the onset of seizures. The patient with eclampsia may appear to cease breathing, then suddenly take a deep, stertorous breath and resume breathing. The patient may then lapse into a coma, lasting a few minutes to several hours. Awakening from the coma, the patient may have no memory of the seizure. Mild eclampsia may involve more than one seizure; severe eclampsia up to 20 seizures.

In eclampsia, physical examination findings are similar to those in preeclampsia but more severe. Systolic blood pressure may increase to 180 mm Hg and even to 200 mm Hg. Inspection may reveal marked edema, but some patients exhibit no visible edema.

Diagnostic tests

Laboratory test findings reveal proteinuria (more than 300 mg/24 hours [1+] with preeclampsia, and 5 g/24 hours [5+] or more with severe eclampsia). Test results may suggest HELLP syndrome.

Ultrasonography, stress and nonstress tests, and biophysical profiles aid evaluation of fetal well-being.

Differential diagnosis is used to distinguish the disorder from viral hepatitis, idiopathic thrombocytopenia, cholecystitis, hemolytic uremic syndrome, peptic ulcer, neuroangiopathic syndrome, appendicitis, kidney stones, pyelonephritis, and gastroenteritis.

Treatment

Therapy for patients with preeclampsia is intended to halt the progress of the disorder—specifically, the early effects of eclampsia, such as seizures, residual hypertension, and renal shutdown—and to ensure fetal survival. Some doctors advocate the prompt inducement of labor, especially if the patient is near term; others follow a more conservative approach. Therapy may include:

- *complete bed rest* in the preferred left lateral lying position to enhance venous return
- *antihypertensive drugs*, such as methyldopa and hydralazine
- *magnesium sulfate* to promote diuresis, reduce blood pressure, and prevent seizures if the patient's blood pressure fails to respond to bed rest and antihypertensives and persistently rises above 160/100 mm Hg, or if central nervous system irritability increases.

If these measures fail to improve the patient's condition, or if fetal life is endangered (as determined by stress or nonstress tests and biophysical profiles), cesarean section or oxytocin inducement may be required to terminate the pregnancy.

Emergency treatment of eclamptic seizures consists of immediate administration of magnesium sulfate (I.V. drip), oxygen administration, and electronic fetal monitoring. After the patient's condition stabilizes, cesarean section may be performed.

Adequate nutrition, good prenatal care, and control of preexisting hypertension during pregnancy decrease the incidence and severity of preeclampsia. Early recognition and prompt treatment of preeclampsia can prevent progression to eclampsia.

Nursing diagnoses

- Activity intolerance ▫ Altered tissue perfusion (cerebral, peripheral) ▫ Altered urinary elimination ▫ Anxiety ▫ Fear ▫ Fluid volume excess ▫ Ineffective family coping: Disabling ▫ Ineffective individual coping ▫ Knowledge deficit ▫ Risk for injury ▫ Sensory or perceptual alterations (visual)

Key outcomes

- The patient's vital signs will remain stable.
- The patient's fluid volume will remain within normal parameters.
- The patient will avoid complications.
- The patient's intake will equal her output.
- The patient won't harm herself.
- The patient will maintain orientation to environment.

Nursing interventions

- Monitor the patient regularly for changes in blood pressure, pulse rate, respiratory rate, fetal heart rate, vision, level of consciousness, and deep tendon reflexes and for headache unrelieved by medication. Report changes immediately. Assess these signs before administering medications. (See [Emergency interventions](#).)
- Monitor the extent and location of edema. Elevate affected extremities to promote venous return. Avoid constricting hose, slippers, or bed linens.
- Assess fluid balance by measuring intake and output and by checking daily weight. Insert an indwelling urinary catheter, if necessary.
- Provide a quiet, darkened room until the patient's condition stabilizes and enforce absolute bed rest.
- Provide emotional support for the patient and family. Encourage them to verbalize their feelings. If the patient's condition necessitates premature delivery, point out that infants of mothers with pregnancy-induced hypertension are usually small for gestational age but sometimes fare better than other premature babies of the same weight, possibly because they have developed adaptive responses to stress in utero. Help the patient and family members to develop effective coping strategies.

Patient teaching

- Teach the patient and family members to identify and report signs of preeclampsia and eclampsia, such as headache, weight gain, edema, and oliguria.
- Instruct the patient to maintain bed rest as ordered. Advise her to lie in a left lateral position to increase venous return, cardiac output, and renal blood flow.
- Stress the importance of adequate nutrition in the prenatal period. Advise the patient to avoid foods high in sodium.
- Emphasize the importance of scheduling and keeping prenatal visits.

PREMATURE LABOR

Premature labor—also known as preterm labor—is the onset of rhythmic uterine contractions that produce cervical changes after fetal viability but before fetal maturity. It usually occurs between the 20th and 37th week of gestation. About 5% to 10% of pregnancies end prematurely; about 75% to 85% of neonatal deaths, and many birth defects, result from this disorder.

Fetal prognosis depends on birth weight and length of gestation: Neonates weighing less than 1 lb 10 oz (737 g) and of less than 26 weeks' gestation have a survival rate of about 10%; neonates weighing 1 lb 10 oz to 2 lb 3 oz (737 to 992 g) and of 27 to 28 weeks' gestation have a survival rate of more than 50%; those weighing 2 lb 3 oz to 2 lb 11 oz (992 to 1,219 g) and of more than 28 weeks' gestation have a 70% to 90% survival rate.

Causes

Premature labor may result from premature rupture of the membranes (occurs in 30% to 50% of premature labors), pregnancy-induced or chronic hypertension, hydramnios, multiple pregnancy, placenta previa, abruptio placentae, incompetent cervix, abdominal surgery, trauma, structural uterine anomalies, infections, hormonal imbalance, genetic defects, and fetal death.

Numerous maternal risk factors also increase the incidence of premature labor. (See [Risk factors for premature labor.](#))

Complications

Premature labor is a major cause of perinatal morbidity and mortality. Respiratory distress syndrome and intracranial bleeding are the primary neonatal complications.

Risk factors for premature labor

The following factors may increase a pregnant patient's risk of premature labor:

- u diethylstilbestrol exposure
- u habitual abortion
- u heavy work and long travel to work
- u history of cone biopsy of the cervix
- u history of genitourinary infections or renal disease
- u history of induced abortion, preterm delivery, or perinatal death
- u low socioeconomic class
- u maternal undernutrition and inadequate weight gain during pregnancy
- u multiple gestation
- u multiple or large uterine leiomyomas
- u single parenthood
- u smoking
- u substance abuse
- u uterine or cervical abnormalities.

Assessment findings

The patient reports the onset of rhythmic uterine contractions, possible rupture of membranes, passage of the cervical mucus plug, and a bloody discharge. Her history indicates that she's in the 20th to 37th week of pregnancy. Inspection during vaginal examination shows cervical effacement and dilation.

Diagnostic tests

Premature labor is confirmed by the combined results of prenatal history, physical examination, and presenting signs and symptoms. Various diagnostic studies support the diagnosis.

Ultrasonography is used to identify the position of the fetus in relation to the mother's pelvis, document gestational age, and estimate fetal weight.

Vaginal examination is used to confirm progressive cervical effacement and dilation.

Electronic fetal monitoring confirms rhythmic uterine contractions and is used to monitor fetal well-being. Ambulatory home monitoring with a tocodynamometer may identify preterm contractions.

Differential diagnosis excludes Braxton Hicks contractions and urinary tract infection.

Treatment

Medical management focuses on suppressing premature labor when tests show immature fetal pulmonary development, cervical dilation of less than 4 cm, and factors that warrant continuation of pregnancy.

Primary interventions include bed rest and hydration. If the patient doesn't respond, tocolytic therapy is instituted unless contraindicated. Beta-adrenergic stimulants (terbutaline, isoxsuprine, or ritodrine) stimulate the beta₂ receptors, inhibiting the contractility of uterine smooth muscle.

Magnesium sulfate may be used to relax the myometrium. After successful tocolysis, oral therapy is maintained until 36 weeks' gestation. Some patients successfully deliver at term after this treatment. Glucocorticoid administration to the mother at less than 33 weeks' gestation enhances fetal pulmonary maturation and reduces the incidence of respiratory distress syndrome.

Ideally, treatment for active premature labor should take place in a regional perinatal intensive care center, where the staff is specially trained to handle this situation. Regardless of where treatment and delivery take place, they require intensive team effort, focusing on:

- u continuous fetal monitoring
- u avoidance of amniotomy, if possible, to prevent cord prolapse or damage to the fetus's soft skull
- u maintenance of adequate hydration through I.V. fluids
- u avoidance of sedatives and narcotics that might harm the fetus.

ALERT Morphine or meperidine may be required to minimize maternal pain. These drugs have little effect on uterine contractions, but because they depress the central nervous system (CNS), they may cause fetal respiratory depression. They should be given in the smallest dose possible and only when needed.

Prevention of premature labor requires good prenatal care, adequate nutrition, and proper rest. Insertion of a purse-string suture (cerclage) to reinforce an incompetent cervix at 14 to 18 weeks' gestation may prevent premature labor in patients with histories of this disorder.

Nursing diagnoses

u Altered family processes u Anxiety u Dysfunctional grieving u Fear u Fluid volume deficit u Ineffective breathing pattern u Ineffective family coping: Disabling u Ineffective individual coping u Pain

Key outcomes

- u The patient will express feelings of comfort.
- u The patient's breathing pattern will become regular and within 5 breaths of baseline.
- u The patient's vital signs will remain stable.

- u The patient's fluid volume will remain within normal parameters.
- u The patient will express feelings about her situation.
- u The patient will use available support systems, such as family and friends, to aid in coping.
- u The patient and family members will seek support groups or professional counselors to aid in coping.

Nursing interventions

- u During attempts to suppress premature labor, maintain bed rest and administer medications as ordered. Give sedatives and analgesics sparingly, mindful of their potentially harmful effect on the fetus. Minimize the need for these drugs by providing comfort measures, such as frequent repositioning and good perineal and back care.
- u When giving beta-adrenergic stimulants, sedatives, and narcotics, monitor blood pressure, pulse rate, respirations, fetal heart rate, and uterine contraction pattern. Minimize adverse effects by keeping the patient in a lateral recumbent position as much as possible. Provide adequate hydration.
- u When giving magnesium sulfate, monitor neurologic reflexes and be alert for maternal adverse effects, such as tachycardia and hypotension. Keep calcium gluconate at the bedside. Watch the neonate for signs of magnesium toxicity, including neuromuscular, respiratory, and CNS depression and decreased sucking reflex.
- u During active premature labor, remember that the premature infant has a lower tolerance for the stress of labor and is much more likely to become hypoxic than the term infant. If necessary, give oxygen to the patient through a nasal cannula. Encourage her to lie on her left side or sit up during labor; these positions prevent caval compression, which can cause supine hypotension and subsequent fetal hypoxia. Observe fetal response to labor through continuous fetal monitoring. Fetal heart rate patterns that are relatively innocuous in term infants may be ominous in preterm infants.
- u Prevent maternal hyperventilation; use a rebreathing bag, if necessary. Continually reassure the patient throughout labor to help reduce her anxiety.
- u Help the patient get through labor with as little analgesic and anesthetic as possible. To minimize fetal CNS depression, avoid administering analgesics when delivery seems imminent. Monitor fetal and maternal response to local and regional anesthetics.
- u During delivery, instruct the patient to push only during the contractions and only as long as instructed. Pushing between contractions is ineffective and can damage the premature infant's soft skull.
- u Notify an anesthesiologist or anesthetist and a pediatrician to be in attendance to care for the premature infant immediately after delivery. Prepare resuscitation equipment and notify the neonatal intensive care unit.
- u Encourage the patient and family members to discuss their feelings. Offer emotional support and help them to develop effective coping strategies.
- u If possible, arrange for the parents to see and hold the infant soon after delivery to promote bonding.

Patient teaching

- u After delivery, inform the parents about their child's condition. Describe his appearance and explain the purpose of any supportive equipment. Help them gain confidence in their ability to care for the child. Provide privacy and encourage them to hold and feed the infant, when possible.
- u As necessary, before the parents leave the hospital with the infant, refer them to a home health nurse who can help them adjust to caring for a premature infant. Encourage them to contact and join community support groups for premature infants and their families.

PREMATURE RUPTURE OF THE MEMBRANES

Premature rupture of the membranes is a spontaneous break or tear in the amniotic sac before onset of regular contractions, resulting in progressive cervical dilation. This common abnormality of parturition occurs in nearly 10% of all pregnancies over 20 weeks' gestation, and labor usually starts within 24 hours; more than 80% of these infants are mature.

The latent period (between membrane rupture and onset of labor) is generally brief when the membranes rupture near term. When the infant is premature, the latent period is prolonged, which increases the risk of mortality from maternal infection (amnionitis, endometritis), fetal infection (pneumonia, septicemia), and prematurity.

Causes

Although the cause of premature rupture is unknown, malpresentation and a contracted pelvis commonly accompany the rupture. Predisposing factors may include poor nutrition and hygiene and lack of prenatal care, an incompetent cervix, increased intrauterine tension due to hydramnios or multiple pregnancies, defects in the amniotic membrane, and uterine, vaginal, and cervical infections (most commonly groups B streptococci, gonococci, and chlamydiae and anaerobic organisms).

Complications

Maternal complications associated with premature rupture of the membranes include cesarean delivery, endometritis, amnionitis and, if untreated, septic shock and death. Neonatal complications include an increased incidence of respiratory distress syndrome, asphyxia, pulmonary hypoplasia, congenital anomalies, malpresentation, and cord prolapse. Severe fetal distress may result in neonatal death.

Assessment findings

A patient who has experienced premature rupture typically reports gushing or leaking of blood-tinged amniotic fluid containing vernix particles. Inspection during sterile speculum examination shows amniotic fluid in the vagina.

Diagnostic tests

A characteristic passage of amniotic fluid confirms the rupture. Slight fundal pressure or Valsalva's maneuver may expel fluid through the cervical os. The following diagnostic tests support the diagnosis:

- u Alkaline pH of fluid collected from the posterior fornix turns nitrazine paper deep blue. (The presence of blood can give a false-positive result.) Staining the fluid with Nile blue sulfate reveals two categories of cell bodies. Blue-stained bodies represent sheath fetal epithelial cells; orange stained bodies originate in sebaceous glands. Incidence of prematurity is low when more than 20% of cells stain orange.
- u A smear of fluid, placed on a slide and allowed to dry, takes on a fernlike pattern (because of the high sodium and protein content of amniotic fluid). This positive finding confirms that the substance is amniotic fluid.
- u Vaginal probe ultrasonography may be done to visualize the amniotic sac.
- u Differential diagnosis excludes urinary incontinence and vaginal infection.

Treatment

Fetal age and the risk of infection are considered in determining the course of treatment for premature rupture of the membranes.

In a term pregnancy, if spontaneous labor and vaginal delivery aren't achieved within 24 hours after the membranes rupture, inducement of labor with oxytocin is usually necessary; if inducement fails, cesarean delivery is usually necessary. Cesarean hysterectomy is recommended with gross uterine infection.

Management of a preterm pregnancy of less than 34 weeks is controversial; with advanced technology, a conservative approach may be effective. With a preterm pregnancy of 28 to 34 weeks, treatment includes hospitalization and observation for signs of infection (maternal leukocytosis or fever and fetal tachycardia) while awaiting fetal maturation. If clinical status suggests infection, baseline cultures and sensitivity tests are appropriate. If these tests confirm infection, labor must be induced, followed by I.V. administration of antibiotics. A culture should also be made of gastric aspirate or a swabbing from the neonate's ear because antibiotic therapy may be indicated for him as well.

During delivery, resuscitative equipment and anesthesia should be available. A pediatrician should be present to treat neonatal distress.

Nursing diagnoses

- u Anxiety
- u Dysfunctional grieving
- u Ineffective family coping: Disabling
- u Ineffective individual coping
- u Knowledge deficit
- u Risk for infection

Key outcomes

- u The patient will remain free from signs and symptoms of infection.
- u The patient will express feelings about her situation.
- u The patient will use available support systems, such as family and friends, to aid in coping.
- u The patient and family members will express understanding of the current condition and treatment.

Nursing interventions

- u During the examination, stay with the patient and offer reassurance. Provide sterile gloves and sterile lubricating jelly. Don't use iodophor antiseptic solution; it discolors nitrazine paper and makes pH determination impossible.
- u After the examination, provide proper perineal care.
- u Send fluid specimens to the laboratory promptly because bacteriologic studies need immediate evaluation.
- u If labor starts, observe the mother's contractions and monitor vital signs every 2 hours. Watch for signs of maternal infection (fever, abdominal tenderness, and changes in amniotic fluid, such as purulence or foul odor) and fetal tachycardia. (Fetal tachycardia may precede maternal fever.) Report such signs immediately.
- u Encourage the patient and family members to express their feelings and concerns for the infant's health and survival.

Patient teaching

- u Teach the patient in the early stages of pregnancy how to recognize premature rupture of the membranes. Make sure she understands that amniotic fluid doesn't always gush; it sometimes leaks slowly.
- u Stress that she must report premature rupture immediately because prompt treatment may prevent dangerous infection.
- u Warn the patient not to engage in sexual intercourse, douche, or take tub baths after the membranes rupture.

PUERPERAL INFECTION

Puerperal infection—a common cause of childbirth-related death—is an inflammation of the birth canal after birth or abortion. It can occur as localized lesions of the perineum, vulva, and vagina, or it may spread, causing endometritis, parametritis, pelvic and femoral thrombophlebitis, peritonitis, and life-threatening endomyoparametritis. In the United States, puerperal infection develops in about 6% of maternity patients. The prognosis is good with treatment.

Causes

Causative microorganisms include streptococci, coagulase-negative staphylococci, *Clostridium perfringens*, *Bacteroides fragilis*, and *Escherichia coli*. Most of these organisms are considered normal vaginal flora but are known to cause puerperal infection in the presence of certain predisposing factors. (See [Risk factors for puerperal infection.](#))

Risk factors for puerperal infection
<p>The following factors increase the risk of puerperal infection:</p> <ul style="list-style-type: none">u anemiau cesarean sectionu frequent vaginal examinations during laboru intercourse after rupture of membranesu invasive techniques such as midforceps deliveryu manual removal of the placentau poor maternal nutritionu poor hygieneu premature or prolonged rupture of membranesu prolonged internal fetal monitoringu prolonged laboru retained placental fragments.

Complications

Any puerperal infection can lead to systemic infection, resulting in septicemia, bacteremic shock, and death. Other complications include pulmonary embolus, cardiac arrest, and cerebrovascular accident.

Assessment findings

Typically, the history reveals a temperature of at least 100.4° F (38° C) developing 2 to 3 days postpartum, or on any 2 consecutive days up to the 11th day, exclusive of the first 24 hours. (Fever during the first 24 hours postpartum may be from dehydration.) The fever can increase to as high as 105° F (40.6° C). The patient may also report chills, headache, malaise, restlessness, and anxiety.

With local lesions of the perineum, vulva, and vagina, the patient may complain of pain and dysuria. Inspection may disclose inflammation and edema of the affected area and profuse purulent discharge.

A patient with endometritis may present with a backache and severe uterine contractions that persist after childbirth. Inspection finds heavy, sometimes foul-smelling lochia. Palpation reveals a tender, enlarged uterus.

With parametritis (pelvic cellulitis), the history may include vaginal tenderness and abdominal pain and tenderness (pain may become more intense as infection spreads). In pelvic thrombophlebitis, the history may reveal severe, repeated chills and dramatic swings in body temperature. The patient may complain of lower abdominal or flank pain. Palpation may reveal a tender mass over the affected area, which usually develops near the second postpartum week.

A patient with femoral thrombophlebitis may report pain, stiffness, or swelling in a leg or the groin. Malaise, fever, and chills usually begin 10 to 20 days postpartum. Inspection reveals inflammation or a shiny, white appearance of the affected leg. Palpation detects Rielander's sign (palpable veins inside the calf and thigh). Examination also may provoke Payr's sign (pain in the calf when pressure is applied to the inside of the foot) and Homans' sign (pain on dorsiflexion of the foot with the knee extended). These signs may precede pulmonary embolism.

In peritonitis, fever accompanies tachycardia (over 140 beats/minute) and a weak pulse. The patient may complain of hiccups, nausea, vomiting, and diarrhea, as well as constant, possibly excruciating, abdominal pain.

Diagnostic tests

Development of the typical clinical features, especially fever within 48 hours after delivery, suggests a puerperal infection. Extrapelvic causes of fever (breast engorgement, mastitis, pneumonia, pyelonephritis, and wound infection) should be ruled out in the initial evaluation.

Culture of lochia, blood, incisional exudate (from cesarean incision or episiotomy), uterine tissue, or material collected from the vaginal cuff, revealing the causative organism, is used to confirm the diagnosis.

White blood cell count 36 to 48 hours postpartum usually reveals leukocytosis (15,000 to 30,000/μl) and an increased erythrocyte sedimentation rate.

Pelvic examination shows induration without purulent discharge in parametritis.

Culdoscopy shows pelvic adnexal induration and thickening. Red, swollen abscesses on the broad ligaments are even more serious, because rupture leads to peritonitis.

Venography and Doppler ultrasonography help to confirm pelvic or femoral thrombophlebitis.

Differential diagnosis excludes cystitis, pyelonephritis, appendicitis, pelvic thrombophlebitis (septic), paralytic ileus, viral syndrome and mastitis.

Treatment

Therapy usually begins with I.V. infusion of a broad-spectrum antibiotic to control the infection while awaiting culture results. After identification of the infecting organism, a more specific antibiotic should be administered. (An oral antibiotic may be prescribed after discharge.)

Ancillary measures include analgesics for pain; anticoagulants, such as I.V. heparin, for thrombophlebitis and endometritis (after clotting time and partial thromboplastin time determine dosage); antiseptics for local lesions; and emetics for nausea and vomiting from peritonitis. Isolation or transfer from the maternity unit also may be indicated.

Supportive care includes bed rest, adequate fluid intake, I.V. fluids when necessary, and measures to reduce fever. Sitz baths and heat lamps may relieve discomfort from local lesions. Surgery may be needed to remove any remaining products of conception or to drain local lesions, such as an abscess in parametritis.

Management of femoral thrombophlebitis requires warm soaks, elevation of the affected leg to promote venous return, and observation for signs of pulmonary embolism.

Nursing diagnoses

- u Altered parenting
- u Anxiety
- u Fluid volume deficit
- u Infection
- u Knowledge deficit
- u Pain
- u Risk for impaired skin integrity

Key outcomes

- u The patient's vital signs will remain stable.
- u The patient's fluid volume will remain within normal parameters.
- u The patient will express feelings of comfort.
- u The patient's skin integrity will remain intact.
- u The patient will be involved in planning her own care.

Nursing interventions

- u Monitor vital signs every 4 hours (more frequently if peritonitis has developed), as well as intake and output. Enforce strict bed rest.
- u Frequently inspect the perineum. Assess the fundus and palpate for tenderness (subinvolution may indicate endometritis). Note the amount, color, and odor of vaginal drainage and document your observations.
- u Administer antibiotics and analgesics as ordered. Assess and document the type, degree, and location of pain, as well as the patient's response to analgesics. Give antiemetics to relieve nausea and vomiting as necessary.
- u Provide sitz baths and a heat lamp for local lesions. Change bed linens and perineal pads frequently. Keep the patient warm.
- u Elevate a thrombophlebitic leg about 30 degrees. Don't rub or manipulate it or compress it with bed linens. Provide warm soaks for the leg. Watch for signs of pulmonary embolism, such as dyspnea and chest pain.
- u Offer reassurance and emotional support. Encourage the patient and family members to express their concerns and help them develop effective coping strategies.
- u If the mother is separated from her infant, keep her informed about his progress. Also encourage the father to reassure the mother about the infant's condition.

To prevent puerperal infection:

- u Maintain aseptic technique when performing a vaginal examination. Limit the number of vaginal examinations performed during labor.
- u Use meticulous hand-washing technique after each patient contact.
- u Keep the episiotomy site clean and provide good perineal hygiene and skin care.
- u Screen personnel and visitors to keep persons with active infections away from the patient.

Patient teaching

- u Instruct all pregnant patients to call their doctors immediately when their membranes rupture. Warn them to avoid intercourse after rupture or leak of the amniotic sac.
- u Teach patients good hand-washing technique and perineal hygiene to prevent infection.

Breast disorders

Some breast disorders, such as mastitis, result from infection and usually affect lactating women. Others, such as galactorrhea, result from hormonal dysfunction unrelated to lactation.

GALACTORRHEA

Inappropriate breast milk secretion, or galactorrhea, may occur 3 to 6 months after the discontinuation of breast-feeding (usually after a first delivery). It's also known as hyperprolactinemia. This disorder may follow an abortion or may develop in a female who hasn't been pregnant; it rarely occurs in males. (Some degree of galactorrhea normally occurs for 3 weeks after weaning.)

Causes

Galactorrhea usually develops in a person with increased prolactin secretion from the anterior pituitary gland, with possible abnormal patterns of secretion of growth, thyroid, and adrenocorticotrophic hormones and disruption of the menstrual cycle. However, increased serum prolactin doesn't always cause galactorrhea. Additional

precipitating factors include:

- *endogenous factors*, including pituitary, ovarian, or adrenal gland tumors and hypothyroidism. In males, galactorrhea usually results from pituitary, testicular, or pineal gland tumors.
- *idiopathic factors*, possibly from stress or anxiety, which cause neurogenic depression of the prolactin-inhibiting factor.
- *exogenous factors*, such as breast stimulation, genital stimulation, or drugs (such as oral contraceptives, meprobamate, and phenothiazines).

Differential diagnosis should rule out pituitary tumor, hypothyroidism, renal disease, prolactinoma, chest lesions, and nonpituitary prolactin-producing tumors.

Complications

When galactorrhea stems from a pituitary gland tumor, possible complications may include increased intracranial pressure, central nervous system (CNS) disturbances, or visual field disturbances.

Assessment findings

Usually, a woman with galactorrhea reports that her breast milk continues to flow after the 21-day period that is normal after weaning. The flow may be spontaneous and unrelated to normal lactation, or it may result from manual expression. Typically, she reports that both breasts are affected. She may also report amenorrhea.

Diagnostic tests

Galactorrhea is determined by palpating the breast from the periphery toward the nipple in an attempt to express any secretion. The diagnosis is confirmed by microscopic observation of multiple fat droplets in the fluid. (A computed tomography scan and, possibly, a mammogram may be ordered to rule out tumors.)

Treatment

The underlying cause is considered in determining the course of treatment, which ranges from simple avoidance of precipitating exogenous factors, such as drugs, to treatment of tumors with surgery, radiation, or chemotherapy.

The choice of therapy for idiopathic galactorrhea depends on whether the patient plans to have more children. If she does, treatment usually consists of bromocriptine; if she doesn't, oral estrogens (such as ethinyl estradiol) and progestins (such as progesterone) are used to effectively treat this disorder. After treatment with bromocriptine, milk secretion usually stops in 1 to 2 months and menstruation recurs after 6 to 24 weeks. Idiopathic galactorrhea may recur after discontinuation of drug therapy.

Nursing diagnoses

- Body image disturbance
- Ineffective individual coping
- Knowledge deficit

Key outcomes

- The patient will express feelings about her situation.
- The patient and family members will express understanding of the disorder and treatment.
- The patient will express positive feelings about self.
- The patient will use available support systems, such as family and friends, to aid in coping.

Nursing interventions

- Monitor for CNS abnormalities, such as headache, failing vision, and dizziness, which may indicate enlarging microadenoma of the pituitary gland.
- Maintain adequate fluid intake, especially if the patient has a fever. However, advise her to avoid caffeine and certain tranquilizers that may aggravate engorgement.
- Encourage the patient to express her feelings about the disorder. Offer emotional support and reassurance.
- Help her develop effective coping strategies.

Patient teaching

- Instruct the patient to keep her breasts and nipples clean. Teach meticulous hand-washing technique.
- Tell the patient who is taking bromocriptine to report nausea, vomiting, dyspepsia, loss of appetite, dizziness, fatigue, numbness, and hypotension. To prevent GI upset, advise her to eat small meals frequently and to take this drug with dry toast or crackers.

MASTITIS

Parenchymatous inflammation of the mammary glands, or mastitis, occurs postpartum in about 1% of lactating women, mainly in primiparas who are breast-feeding. It occurs occasionally in nonlactating women and rarely in men. The prognosis is good.

Causes

Mastitis develops when a pathogen that typically originates in the nursing infant's nose or pharynx invades breast tissue through a fissured or cracked nipple and disrupts normal lactation. The most common pathogen is *Staphylococcus aureus*; less frequently, it's *S. epidermitis* or beta-hemolytic streptococci. Rarely, mastitis may result from disseminated tuberculosis or the mumps virus.

Predisposing factors include a fissure or abrasion of the nipple, blocked milk ducts, and an incomplete letdown reflex. Blocked milk ducts can result from a tight bra or prolonged intervals between breast-feedings.

Complications

An untreated breast infection can lead to abscess.

Assessment findings

Usually, the patient reports a fever of 101° F (38.3° C) or higher in acute mastitis, malaise, and flulike symptoms that develop 2 to 4 weeks postpartum, although they may develop anytime during lactation. Inspection and palpation may uncover redness, swelling, warmth, hardness, tenderness, nipple cracks or fissures, and enlarged axillary lymph nodes.

Diagnostic tests

Cultures of expressed milk are used to confirm generalized mastitis; cultures of breast skin are used to confirm localized mastitis. Such cultures also are used to determine antibiotic therapy. Differential diagnosis should exclude breast engorgement, breast abscess, viral syndrome, and a clogged duct.

Treatment

Antibiotic therapy, the primary treatment, usually consists of penicillin G to combat staphylococci; erythromycin or kanamycin is used for penicillin-resistant strains. A cephalosporin or dicloxacillin is also used. Symptoms usually subside in 2 to 3 days, but antibiotics should continue for 10 days. Other measures include analgesics and, rarely, breast abscess incision and drainage.

HOME CARE

Preventing mastitis

To help your patient prevent mastitis from recurring, follow these guidelines:

- u Stress the importance of emptying the breasts completely because milk stasis can cause infection and mastitis.
- u Teach the patient to alternate feeding positions and to rotate pressure areas on the nipples.
- u Remind the patient to position the infant properly on the breast with the entire areola in his mouth.
- u Advise her to expose sore nipples to the air as often as possible.
- u Teach the patient proper hand-washing technique and personal hygiene.
- u Instruct her to get plenty of rest and consume sufficient fluids and a balanced diet to enhance breast-feeding.
- u Suggest applying a warm, wet towel to the affected breast or taking a warm shower to relax and improve breast-feeding.

Nursing diagnoses

- u Ineffective breast-feeding u Infection u Knowledge deficit u Pain u Risk for impaired skin integrity

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will resume breast-feeding without further complications.
- u The patient's skin integrity will remain intact.

Nursing interventions

- u Give analgesics as needed.
- u Provide comfort measures, such as warm soaks.
- u Use meticulous hand-washing technique and provide good skin care.

Patient teaching

- u Tell the patient to take the antibiotic *exactly* as prescribed, even if her symptoms subside.
- u Reassure the mother that breast-feeding won't harm her infant because he's the source of the infection. If only one breast is affected, advise the patient to offer the infant that breast first to promote complete emptying and prevent clogged ducts. However, if an open abscess develops, she must stop breast-feeding with this breast and use a breast pump until the abscess heals. She should continue to breast-feed on the unaffected side.
- u Show how to position the infant properly to prevent cracked nipples. (See [Preventing mastitis.](#))

INTRODUCTION

Human beings receive about 70% of all sensory information through the eyes. That is why health care professionals need to urge patients to seek routine ophthalmologic examinations. It's important for patients to receive early treatment for vision problems to correct impaired vision and avoid blindness. (See [Leading causes of blindness.](#))

The ocular system consists of the bony orbit that houses the eye; the contents of the orbit, including the eyeball, optic nerve, extraocular muscles, cranial nerves (III, IV, and VI), blood vessels, orbital fat, and lacrimal system; and the eyelid that protects and covers the eye. (See [Cross section of the eye.](#))

The *orbit* (or socket) encloses the eyeball in a protective recess in the skull. The seven bones of the orbit—the frontal, sphenoid, zygomatic, maxilla, palatine, ethmoid, and lacrimal bones—form a cone, with the apex pointing toward the brain; the base of the cone forms the orbital rim. The periorbita covers the orbital bones. The thinness of the orbital wall makes this area especially vulnerable to fractures.

Various extraocular muscles hold the eyeball in place and control its movement. These muscles include the following:

- u *superior rectus*, which rotates the eye upward as well as adducts and rotates it inward
- u *inferior rectus*, which rotates the eye downward as well as adducts and rotates it outward
- u *lateral rectus*, which turns the eye outward (laterally)
- u *medial rectus*, which turns the eye inward (medially)
- u *superior oblique*, which turns the eye downward and abducts and rotates it inward
- u *inferior oblique*, which turns the eye upward and abducts and turns it outward.

The actions of these muscles are mutually antagonistic. As one contracts, its opposing muscle relaxes.

Ocular layers

The eye has three structural layers: the sclera and cornea, the uveal tract, and the retina.

Corneoscleral layer

The *sclera* is a dense, white, fibrous protective tissue that surrounds the eyeball and continues as the cornea at the limbus (corneoscleral junction) anteriorly and into the dural sheath of the optic nerve posteriorly. There, a few strands of scleral tissue form a sievelike structure (the lamina cribrosa) that makes a passage for the ganglionic cell axons. (On examination, this area appears as the optic disk.) The episclera, a thin layer of fine elastic tissue, covers the sclera.

The *cornea* is continuous with the sclera. This transparent, avascular, and curved structure has five layers:

- u the epithelium, which contains sensory nerves
- u Bowman's membrane, which is the basement membrane for the epithelial cells
- u the stroma, which makes up the supporting tissue (90% of the cornea)
- u Descemet's membrane, which provides elasticity
- u the endothelium, which acts as a pump to maintain proper intraocular pressure, thereby preventing corneal turgescence (or distention).

Bathing the posterior surface of the cornea, aqueous humor maintains intraocular pressure by its volume and flow rate. Tears bathe and moisten the anterior cornea. The cornea's only function is to refract light.

Uveal layer

The *uveal tract* is the pigmented, vascular middle layer of the eye. It contains the iris and the ciliary body in the anterior portion and the choroid in the posterior portion.

The *iris* is a circular contractile disk. Centered in the iris is the pupil. Light entering the eye passes through the pupil. Sphincter and dilator muscles of the iris control the amount of light entering the eye. The pupil controls the flow of aqueous humor from the posterior to the anterior chamber.

The anterior iris joins the posterior corneal surface at an angle. Here, many tiny collecting channels form the trabecular meshwork. Aqueous humor drains through these channels into an encircling venous system called Schlemm's canal.

The *ciliary body*—extending from the root of the iris to the ora serrata—produces aqueous humor and controls lens shape (accommodation) by its action on the zonular fibers.

The *choroid*, the largest part of the uveal tract, is made of blood vessels bound externally by the suprachoroid and internally by Bruch's membrane. Extending from the ora serrata to the optic nerve and attached to Bruch's membrane are the retina and the retinal pigment epithelium (RPE).

Leading causes of blindness
<p>In the United States, a person is considered legally blind if he has optimal visual acuity of 20/200 or less in the better eye after best correction or a visual field not exceeding 20 degrees in the better eye.</p> <p>The most common causes of acquired blindness include glaucoma, age-related macular degeneration, and diabetic retinopathy. The incidence of blindness from glaucoma is decreasing, most likely a result of early detection and treatment.</p> <p>Rare causes of acquired blindness include herpes simplex, keratitis, cataracts, and retinal detachment.</p>
Causes worldwide
<p>The most common causes of preventable blindness worldwide are trachoma, cataracts, onchocerciasis (microfilarial infection transmitted by blackflies and other species of <i>Simulium</i>), and xerophthalmia (dryness of conjunctiva and cornea from vitamin A deficiency).</p>

Retinal layer

The *retina* receives visual images and transmits them to the brain for interpretation. Although it holds no pain fibers, the retina is a multilayered sheet of neural tissue. It attaches to a layer of pigmented epithelial cells, the RPE, which adheres lightly to the choroid. Beside and beneath the RPE are rods and cones. These light receptors perceive light and process it in different ways. Rods, scattered throughout the retina, respond to low light levels and detect moving objects; cones, located in the fovea centralis, function best in brighter light and perceive finer details.

Three types of cones contain different visual pigments and react to specific light wavelengths; one type reacts to red light, one to green, and one to blue-violet. The eye mixes these colors into various shades; the cones can detect 150 shades.

The lens and accommodation

The *lens* of the eye is biconvex, avascular, and transparent; the lens capsule is a semipermeable membrane that can admit water and electrolytes. The lens changes shape for both near and far vision. For near vision, the ciliary body contracts and relaxes the zonular fibers, the lens becomes spherical, the pupil constricts, and the eyes converge. For far vision, the ciliary body relaxes, the zonular fibers tighten, the lens becomes flatter, the pupils dilate, and the eyes straighten. The lens refines the refraction necessary to focus a clear image on the retina.

The *vitreous body*, which is 99% water with a small amount of insoluble protein, makes up two-thirds of the volume of the eye. This gelatinous body gives the eye its shape and contributes to the refraction of light rays. The vitreous is firmly attached anteriorly to the ora serrata of the ciliary body and posteriorly to the optic disk. The vitreous face contacts the lens; the vitreous gel rests against the retina.

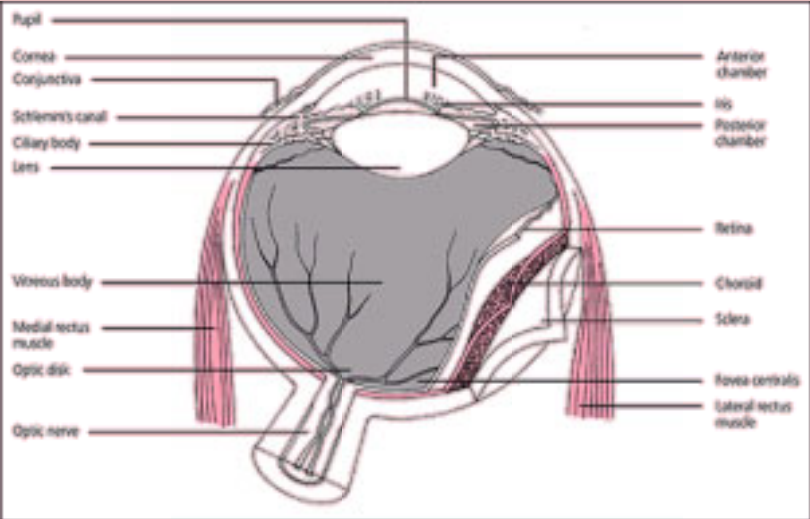

Lacrimal network and eyelids

Tears are secreted by the *lacrimal apparatus*, which consists of the lacrimal gland, upper and lower canaliculi, lacrimal sac, and nasolacrimal duct. The tear gland, located in a shallow fossa beneath the superior temporal orbital rim, secretes fluid to keep the cornea and conjunctiva moist. These tears flow through 8 to 12 excretory ducts and contain lysozyme, an enzyme that protects the conjunctiva from bacteria. With every blink, the eyelids direct the flow to the inner canthus, where the tears pool and then drain through a tiny opening called the punctum. The tears then pass through the canaliculi and lacrimal sac and down the nasolacrimal duct, which opens into the nasal cavity.

The *eyelids* (palpebrae) consist of tarsal plates that are composed of dense connective tissue. The orbital septum—the fascia behind the orbicularis oculi muscle—acts as a barrier between the lids and the orbit. The levator palpebrae muscle raises the upper lid. The eyelids contain three types of glands:

- u *Meibomian glands* are sebaceous glands in the tarsal plates that secrete an oily substance to prevent evaporation of the tear film. The upper eyelid holds about 25 of these glands; the lower lid, about 20.
- u *Glands of Zeis* are modified sebaceous glands connected to the follicles of the eyelashes.
- u *Moll's glands* are ordinary sweat glands.

The *conjunctiva* is the thin mucous membrane that lines the eyelids (palpebral conjunctiva), folds over at the fornix, and covers the surface of the eyeball (bulbar conjunctiva). The ophthalmic and lacrimal arteries supply blood to the lids. The space between the open lids is the palpebral fissure; the juncture of the upper and lower lids is the canthus. The junction near the nose is called the nasal, medial, or inner canthus; the junction on the temporal side, the lateral or external canthus.

Cross section of the eye

Depth perception

In normal binocular vision, a perceived image is projected onto the two foveae. Impulses then travel along the optic pathways to the occipital cortex, which perceives a single image. However, the cortex receives two images—each from a slightly different angle—giving the images perspective and depth.

Patient history and physical examination

Begin by asking the patient to describe any current eye problems. Ask specifically if he's had blurred vision, floaters, halos, pain, or infection and whether these affect one or both eyes. Ask whether he wears, or has worn, eyeglasses or contact lenses. If so, ask him when his prescription last changed.

Find out whether he has health problems, such as hypertension or diabetes. Ask whether he takes any prescription medications or whether he has had eye surgery. Also investigate family members' history for cataracts, glaucoma, or blindness.

Finally, explore the patient's social and work environments to detect potential causes of eye disorders. For example, extensive reading, lack of sleep, or the use of video display terminals may strain the eyes and cause dryness. Exposure to cigarette smoke, chemicals, or glues can irritate the eyes.

CULTURAL TIP Examine the patient's beliefs about the disorder and the influence of these beliefs on his health. For example, ask the patient how he feels or what he believes about his change in vision. (What do you think may have contributed to this disorder?) His response may indicate that it was destined to happen (religious belief) or that someone (deity) has cursed him (evil eye, or something similar). Try to help change his false beliefs, if possible.

Throughout the interview, observe the patient's eye movements and ability to focus for clues to eye muscle coordination and visual acuity. Note the appearance of the eyelids, eyelashes, eyeballs, and lacrimal apparatus. Do the eyelids close completely over the sclera? Is eyelid color consistent with the patient's complexion? Are the eyelashes equally distributed along the upper and lower eyelid margins, and do they curve appropriately? Do the eyes tear normally, or does the patient complain of dryness or excessive tearing? Is the punctum free of inflammation or swelling?

Examine the conjunctiva and sclera. The conjunctiva should be clear and the sclera white, although small, dark spots occur normally on the sclera of dark-skinned persons, such as those of African or Mediterranean ancestry.

Inspect the iris, noting its shape and color. Check the anterior chamber and cornea to determine if they're clear and transparent, and confirm that the cornea is shiny and bright, free of scars and other irregularities.

Check both pupils for equality of size and shape. Note pupillary reaction to light and accommodation.

After completing your inspection, gently palpate the eyelids, noting any swelling or complaints of tenderness. Extend the palpation to include the eyeballs, which should feel equally firm.

Palpate the lacrimal sac while observing the punctum. Excessive tearing or regurgitation of purulent material may indicate a blockage of the nasolacrimal duct.

Diagnostic tests

Several tests are used to assess visual acuity and identify defects. Color vision testing may be performed to identify color blindness. The patient is shown a series of pseudoisochromatic cardlike plates, such as *Ishihara's* or *Hardy-Rand-Rittler plates*. These test cards have a variegated, colored background and contain a letter, number, or pattern of a slightly different color in the center of each plate. The patient with deficient color perception can't perceive the differences in hue or, consequently, the figures formed by the contrasting colors.

Snellen chart or other eye charts evaluate visual acuity. Such charts use progressively smaller letters or symbols to determine central vision on a numeric scale.

Ophthalmoscopy allows examination of the interior of the eye after the pupil has been dilated with a mydriatic agent.

Refraction tests may be performed with or without cycloplegic agents. In cycloplegic refraction, eyedrops temporarily paralyze the ciliary muscle, thereby causing the pupil to dilate. This dilation lets the examiner identify the error of refraction more accurately.

Maddox rod test is used to assess muscle dysfunction; it's especially useful to disclose and measure heterophoria (the tendency of the eyes to deviate).

Duction test is used to check eye movement in all directions. While one eye is covered, the other eye follows a moving light. This test is used to detect any weakness of rotation caused by muscle paralysis or structural dysfunction.

Test for convergence is used to locate the breaking point of fusion. In this test, the examiner holds a small object in front of the patient's nose and slowly brings it closer to the patient. Normally, the patient can maintain convergence until the object reaches the bridge of the nose. The point at which the eyes “break” is termed the near point of convergence and is measured in centimeters.

Cover-uncover test is used to assess muscle deviation. The patient stares at a small, fixed object, first from a distance of 20' (600 m), then from 1' (305 cm). The examiner covers the patient's eyes one at a time, noting any movement of the uncovered eye, the direction of any deviation, and the rate at which the eyes recover normal binocular vision when latent heterophoria is present.

Slit-lamp examination allows well-illuminated microscopic examination of the eyelids and the anterior segment of the eyeball.

Visual field tests are used to assess the function of the peripheral retina, outline the blind spot (which corresponds to the optic nerve), and define the field defects resulting from lesions along the optic pathways.

Schiøtz tonometry and applanation tonometry are used to measure intraocular pressure. After instilling a local anesthetic in the patient's eye, the examiner places the Schiøtz tonometer lightly on the corneal surface and measures the indentation of the cornea produced by a given weight. Applanation tonometry is used to gauge the force required to flatten, rather than indent, a small area of the central cornea.

Gonioscopy allows for direct visualization of the anterior chamber angle through the use of a goniolens; the slit lamp is the light source and microscope.

Ophthalmodynamometry is used to measure the relative central retinal artery pressures and indirectly assess carotid artery flow on each side.

Fluorescein angiography is used to evaluate blood vessels in the choroid and retina. After I.V. injection of fluorescein dye, rapid-sequence photographs of the fundus record images of the dye-enhanced vasculature.

Ocular ultrasonography involves transmitting high-frequency sound waves into the eye and measuring their echo from ocular structures. A-scan ultrasonography is used to measure axial eye length. B-scan ultrasonography is used to evaluate eye structures and helps to diagnose abnormalities.

Electrophysiology tests, including electroretinogram, electrooculogram, dark adaptometry, and visual evoked potential, are used to assess function of the visual pathways from the photoreceptors of the retina to the visual center in the brain. These examinations are used to diagnose inherited retinal diseases or vascular occlusions and intraocular foreign bodies.

Disorders of the eyelids and lacrimal ducts

Disorders of the eyelids and lacrimal ducts are commonly apparent on examination. Such disorders are caused by a range of factors, from infection to congenital

deformity. They include blepharitis, chalazion, dacryocystitis, orbital cellulitis, ptosis, and stye.

BLEPHARITIS

Blepharitis is a common inflammation of eyelash follicles and meibomian glands of the upper or lower eyelids. It gives a red-rimmed appearance to the eyelid margins. The disorder, which may affect both eyes (and both upper and lower eyelids), tends to recur and may become chronic. Seborrheic (nonulcerative) blepharitis is more common in elderly people but also may affect people with red hair. Staphylococcal (ulcerative) blepharitis may coexist with seborrheic blepharitis. Both types can be controlled if treatment begins before the onset of ocular involvement.

Causes

Seborrheic blepharitis generally results from seborrhea of the scalp, eyebrows, and ears; ulcerative blepharitis, from a *Staphylococcus aureus* infection. (Chalazia and styes are likely to develop with this infection.)

Complications

Without adequate treatment, blepharitis may lead to keratitis.

Assessment findings

The patient typically complains that his eyelids itch, burn, or feel as if they have a foreign body in them. He may also complain that his eyelids are crusty and stick together when he awakens in the morning.

Inspection may reveal that the patient unknowingly rubs his eyes (causing the red rims) or continually blinks. You may also note waxy scales along the eyelids, indicating seborrheic blepharitis. Flaky scales on the eyelashes, missing eyelashes, or ulcerations on eyelid margins suggest ulcerative blepharitis.

Diagnostic tests

A culture of the ulcerated eyelid margin may reveal *S. aureus* in ulcerative blepharitis.

Treatment

Early treatment is essential to prevent recurrence or complications. For patients with seborrheic blepharitis, treatment includes daily shampooing (using a mild shampoo on a cotton-tipped applicator or a washcloth) to remove scales from the eyelid margins. Patients should also shampoo the scalp and eyebrows and follow up with warm eye compresses.

A patient with ulcerative blepharitis requires the same treatment, in addition to a sulfonamide or an appropriate antibiotic eye ointment at bedtime. (See [Instilling an ophthalmic ointment.](#))

A combination antibiotic and steroid, such as prednisone (sulfa and steroid; Vasocidin or Blephamide), may be used.

Treatment for a patient with blepharitis resulting from pediculosis involves removing the nits with forceps or applying ophthalmic physostigmine or other insecticidal ointment.

ALERT Application of ophthalmic physostigmine or other insecticidal ointment can cause pupil constriction, headache, conjunctival irritation, or blurred vision from the film of ointment on the cornea.

Nursing diagnoses

- u Altered health maintenance
- u Body image disturbance
- u Impaired skin integrity
- u Ineffective individual coping
- u Risk for injury

Instilling an ophthalmic ointment

Follow these directions to administer an ophthalmic ointment cleanly and quickly:

- u Tilt the patient's head backward and ask him to look toward the ceiling.
- u Gently pull the lower eyelid down and apply ointment directly onto the exposed conjunctiva from the inner to the outer canthus.
- u Take care to avoid touching the eye with the tip of the ointment tube.
- u Repeat this procedure for the other eye.

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient and family members will verbalize their feelings and concerns.
- u The patient and family members will identify available health resources.
- u The patient and family members will demonstrate appropriate coping skills.

Nursing interventions

u Provide eyelid care at least twice daily. To do so, dip a cotton-tipped applicator in baby shampoo, and then shake the applicator to remove any excess shampoo. Using a downward motion from the eyelid margin to the tips of the eyelashes, gently clean the upper eyelid margin. Repeat on the lower eyelid margin. Use a warm, wet washcloth to rinse the shampoo away.

Patient teaching

- u Encourage the patient to participate in eyelid care.
- u Show him how to use a cotton-tipped applicator or a clean washcloth to remove the scales from his eyelids. Instruct him to do this daily.
- u Demonstrate how to apply warm compresses: First, run warm water into a clean bowl. Then immerse a clean cloth in the water and wring the water from the cloth. Next, place the warm cloth against the closed eyelid. (Be careful not to use hot water, which could burn the skin.) Hold the compress in place until it cools. Continue this procedure for 15 minutes.

CHALAZION

A common eye disorder, a chalazion is a granulomatous inflammation of a meibomian (sebaceous) gland in the upper or lower eyelid. This disorder usually develops slowly over several weeks. A large chalazion seldom subsides spontaneously. Because the upper eyelid holds 25 meibomian glands and the lower eyelid holds 20,

more than one gland can be infected at the same time. Generally benign and chronic, a chalazion can occur at any age.

Causes

Obstruction of the meibomian gland duct causes a chalazion. It may develop as a complication from a hordeolum (stye).

Complications

Untreated, a chalazion may press on the cornea and cause a vision disturbance such as astigmatism.

Assessment findings

The patient may complain of a small bump or lump on the eyelid. Inspection may reveal a small nodule pointing toward the eyelid's conjunctival side. The area may look inflamed. However, if the chalazion has grown large, inflammation may have subsided. (See [Recognizing a chalazior.](#)) On eversion of the eyelid, note a red or red-yellow elevated area on the conjunctival surface. Palpation of the eyelid may disclose a small bump or nodule. The bump isn't tender initially, but it may become tender in later stages.

Diagnostic tests

Recurrent chalazions, especially in an adult, necessitate biopsy to rule out meibomian gland cancer.

Treatment

Initial therapy consists of applying warm compresses to open the glandular lumen and, occasionally, instilling sulfonamide eyedrops. If this therapy fails, if the chalazion presses on the eyeball, or if the swelling causes a cosmetic problem, incision and curettage under local anesthesia may be necessary. Afterward, a pressure patch is applied to the eye for 8 to 12 hours to control bleeding and swelling. When the patch is removed, treatment again involves warm eye compresses applied for 10 to 15 minutes two to four times daily. Antimicrobial eyedrops or eye ointment may be ordered to prevent secondary infection. If this treatment is ineffective, the lesion may be injected with corticoids.

Nursing diagnoses

- u Altered health maintenance
- u Anxiety
- u Body image disturbance
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient and family members will verbalize their feelings and concerns.
- u The patient will regain visual function.

Nursing interventions

- u Instill antimicrobial eyedrops or ointment as ordered.
- u Provide a safe environment by removing excess equipment from the patient's room. Orient him to the room and show him how to use the call button.
- u Assess the patient's visual acuity preoperatively and at the first postoperative visit.

Patient teaching

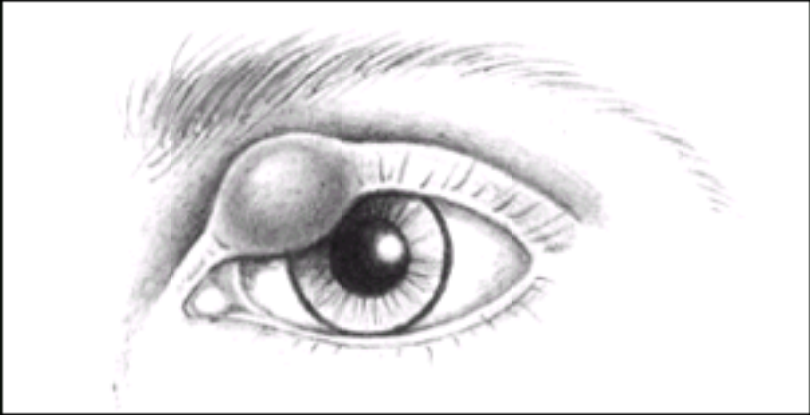

- u Teach the patient about any antimicrobial drugs used to treat the chalazion. Name the drug and its desired actions and discuss its dosage and possible adverse effects. Also, show the patient or a family member how to instill eyedrops. Reinforce your instruction with written information.
- u Teach proper eyelid hygiene to the patient predisposed to chalazia. Show him how to wash his eyelid with water and mild baby shampoo applied with a cotton-tipped applicator.
- u Instruct the patient how to properly apply warm compresses. Caution him not to use hot water, which may burn his skin. Advise him to use a clean compress. Direct him to apply warm compresses at the first sign of eyelid irritation. Explain that this will increase circulation in the area and keep the lumen open.
- u Urge him to keep follow-up appointments.

DACRYOCYSTITIS

A common infection, dacryocystitis may be acute or chronic. In adults, this infection of the lacrimal sac may follow an obstruction (dacryostenosis) of the nasolacrimal duct (most prevalent in women over age 40) or trauma. In infants, it results from congenital atresia of the nasolacrimal duct. Usually unilateral, dacryocystitis can also be bilateral.

Recognizing a chalazion

A chalazion typically appears as a nontender bump on one of the eyelids. Here, a chalazion affects the upper eyelid.

Causes and pathophysiology

The most common infecting organism in acute dacryocystitis is *Staphylococcus aureus* or, occasionally, beta-hemolytic streptococcus. In chronic dacryocystitis, *Streptococcus pneumoniae* or, sometimes, a fungus—such as *Candida albicans*—is responsible for the infection.

In infants, atresia of the nasolacrimal ducts results from failure of canalization or, in the first few weeks of life, from blockage when the membrane between the lower nasolacrimal duct and the inferior nasal meatus fails to open spontaneously before tear secretion.

Complications

Untreated dacryocystitis may result in skin perforation and fistulas.

Assessment findings

The patient typically complains of constant tearing—the hallmark of both acute and chronic dacryocystitis—and tenderness over the lacrimal sac.

In acute disease, pressure applied to the lacrimal sac causes the punctum to produce a purulent discharge. In chronic dacryocystitis, the tear sac produces a mucoid discharge.

Diagnostic tests

Tests used for this condition typically include cultures of exudate to identify the pathogen, typically *S. aureus* and, occasionally, beta-hemolytic streptococcus in acute dacryocystitis and *S. pneumoniae* or *C. albicans* in chronic disease. The white blood cell count may increase in acute disease; it's usually normal in chronic dacryocystitis. Dacryocystography can be used to locate the site of congenital atresia.

Treatment

Topical and systemic antibiotics and warm compresses may relieve acute dacryocystitis. Chronic dacryocystitis may eventually require dacryocystorhinostomy.

For nasolacrimal duct obstruction in an infant, treatment consists of carefully massaging the lacrimal sac area four times daily until the infant is 8 or 9 months old. At that time, the obstruction commonly resolves spontaneously. If massage fails to open the duct, dilating the punctum and probing the duct may be necessary.

Nursing diagnoses

- u Altered health maintenance
- u Altered tissue perfusion
- u Anxiety
- u Impaired gas exchange
- u Impaired tissue integrity
- u Pain
- u Risk for infection

Key outcomes

- u The patient will maintain current health status.
- u The patient will maintain adequate tissue perfusion.
- u The patient will maintain adequate gas exchange.
- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u If the patient will have surgery, encourage him to express any fears related to the procedure.
- u Monitor the postoperative patient for bleeding—a rare complication.
- u Apply ice compresses postoperatively to the affected area.
- u After surgery, assist the patient with pulmonary hygiene to prevent atelectasis.

Patient teaching

- u Instruct the patient with acute dacryocystitis to complete the prescribed course of antibiotic therapy. Give instructions concerning the medication's purpose, dosage, and possible adverse effects.
- u Teach the patient how to apply warm compresses before instilling antibiotic eyedrops.
- u Review reportable signs of worsening infection.
- u If the patient is having surgery for chronic dacryocystitis, tell him to expect blood to ooze from his nose after surgery. To reduce this blood flow, he may have an ice compress applied over the pressure bandage at the incision site. Inform him that he'll lie on the affected side for up to 24 hours after surgery until the bleeding stops. Explain that this position will prevent him from swallowing blood.
- u Advise the patient not to drink hot beverages for the first 3 days after surgery and to avoid alcohol for 2 weeks postoperatively. Warn him not to blow his nose for 1 week after surgery.

ORBITAL CELLULITIS

Orbital cellulitis is an acute infection that involves the fatty orbital tissues and eyelids but not the eyeball. With treatment, the prognosis is good.

Causes

Orbital cellulitis usually results from infection of nearby structures—typically by streptococcal, staphylococcal, and pneumococcal organisms. In children, orbital cellulitis may follow *Haemophilus influenzae* infection. These organisms invade the orbit, commonly by direct extension through the sinuses (especially the ethmoid sinus), the bloodstream, or the lymphatic ducts.

Primary orbital cellulitis results from orbital injury (such as an insect bite) that permits bacterial entry. Although this disease form is common in young children, it also affects people with poor dental hygiene and those who snort cocaine.

Complications

The infection may extend posteriorly, causing cavernous sinus thrombosis, meningitis, or brain abscess and, possibly, death. If the disease leads to optic neuritis, atrophy and subsequent vision loss may occur.

Assessment findings

The patient typically complains of severe orbital pain. He may also report chills, fever, and malaise.

Inspection may reveal chemosis (excessive conjunctival edema) and unilateral eye edema. You may also observe impaired eye movement, hyperemia of the orbital tissue, reddened eyelids, and a purulent ocular discharge that mats the lashes. In advanced orbital cellulitis, examination may reveal proptosis caused by edematous tissues within the bony orbit.

Diagnostic tests

Wound culture and sensitivity testing may be done to identify the infecting organism. A white blood cell count typically reveals leukocytosis.

Treatment

To prevent complications, treatment should begin promptly. Primary treatment consists of systemic oral or I.V. antibiotics and eyedrops or ointment. Supportive treatment consists of bed rest, fluids, and warm, moist eye compresses. If cellulitis fails to respond to antibiotics after 3 days, incision and drainage may be necessary.

Nursing diagnoses

- u Altered health maintenance
- u Fear
- u Pain
- u Risk for infection
- u Risk for injury

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient and family members will verbalize their feelings and concerns.

Nursing interventions

- u Monitor vital signs, fluid and electrolyte balance, and visual acuity every 4 hours.
- u Assess the patient's pain level and administer analgesics as prescribed. Monitor their effectiveness.
- u Apply warm compresses every 3 to 4 hours to the inflamed area to relieve discomfort.

Patient teaching

- u Help the patient to identify avoidable hazards that may cause eye injury.
- u Teach him how to apply warm eye compresses.
- u Explain the actions, dosages, routes, and adverse effects of prescribed medications.
- u Before discharge, instruct the patient to complete the full prescribed antibiotic regimen. To prevent recurrent orbital cellulitis, teach him to maintain good general hygiene and to carefully clean abrasions and cuts that occur near the eye. Urge early treatment of orbital cellulitis to prevent the spread of infection.

PTOSIS

A congenital or acquired disorder, ptosis is a drooping upper eyelid that remains lowered despite the patient's effort to raise it. The condition may be unilateral or bilateral, continuous or intermittent. Severe ptosis usually responds well to treatment; slight ptosis may require no treatment at all.

Causes and pathophysiology

Congenital ptosis is transmitted as an autosomal dominant trait, or it results from a congenital anomaly in which the levator muscles of the eyelids fail to develop. Although this condition is usually unilateral, it can be bilateral.

Acquired ptosis may result from:

- u *age* (senile ptosis), which causes loss of levator muscle tone and usually produces bilateral ptosis
- u *mechanical factors* that make the eyelid heavy, such as swelling caused by a foreign body on the eyelid's palpebral surface (other mechanical factors include edema, inflammation produced by a tumor or pseudotumor, or an extra fatty fold)
- u *myogenic factors*, such as muscular dystrophy and myasthenia gravis (in which the defect may involve humoral transmission at the myoneural junction)
- u *neurogenic (paralytic) factors* from interference in eyelid innervation by the oculomotor nerve (cranial nerve III) (this usually results from trauma, diabetes mellitus, or carotid aneurysm; it also may result from an interruption of sympathetic innervation to the eye [resulting in Horner's syndrome with ipsilateral miosis and ptosis])
- u *nutritional factors*, such as a thiamine deficiency caused by chronic alcoholism or other malnutrition-producing states such as hyperemesis gravidarum.

Complications

Ptosis may disturb normal vision.

Assessment findings

In ptosis, findings vary depending on the patient's age. Inspection of the infant with congenital ptosis may reveal a smooth, flat upper eyelid without the tarsal fold normally caused by the pull of the levator muscle. You may also note an associated weakness of the superior rectus muscle. (See [Recognizing ptosis.](#))

The child with unilateral ptosis that covers the pupil may experience amblyopia, possibly from disuse or lack of eye stimulation. If the child has bilateral ptosis, the eyebrow may be elevated or forehead wrinkled because of attempts to raise the upper eyelid. You may also observe the child tilt his head backward to see objects straight ahead.

Recognizing ptosis

A drooping upper eyelid—typically apparent on visual examination—is the hallmark of ptosis. The disorder may affect one or both eyelids.

The adult patient with ptosis may have a history of chronic alcoholism or excessive vomiting. Upon inspection, you may see that one eyelid either covers the patient's iris completely or covers more of the iris than the other eyelid. If the patient has myasthenia gravis, inspection may reveal ptosis that occurs during the evening. You may also observe a fixed, dilated pupil; divergent strabismus; and slight depression of the eyeball.

Diagnostic tests

Measuring palpebral fissure widths and checking the range of eyelid movement help to determine the severity of ptosis.

Other tests are used to determine the underlying cause of the disorder. For instance, the glucose tolerance test may reveal diabetes mellitus. The edrophonium test can confirm myasthenia gravis (in the patient with acquired ptosis and no history of trauma). Ophthalmologic examination may disclose foreign bodies. Magnetic resonance imaging or digital subtraction angiography may reveal an aneurysm.

Treatment

Slight ptosis that doesn't produce deformity or vision loss requires no treatment. Severe ptosis that interferes with vision or disfigures appearance may require surgery to resection weak levator muscles. To correct congenital ptosis, the patient may undergo surgery at age 3 or 4 or earlier if ptosis is unilateral and if pupillary occlusion may cause amblyopia. An alternative to surgery may be special eyeglasses with an attached suspended crutch on the frame to elevate the eyelid.

Effective management also includes treatment of the underlying cause. For example, in myasthenia gravis, neostigmine may be prescribed to enhance innervation to the muscles.

Nursing diagnoses

- u Altered health maintenance
- u Risk for infection
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will explain visual functioning.

Nursing interventions

- u Provide a safe environment by removing excess equipment and furniture from the patient's room.
- u Report postoperative bleeding immediately.
- u Apply ointment to sutures as prescribed.
- u Apply ice compresses to decrease swelling.

Patient teaching

- u After surgery, emphasize the need to protect the surgical site during healing (usually 6 weeks). Explain that injury at the suture line can precipitate recurrent ptosis. Review the signs of infection.
- u If the patient is a young child, encourage his parents to review safety measures with him.

CULTURAL TIP Provide oral and written instructions for using medications, including ophthalmic ointment. Ensure that the patient and family members understand treatment. Don't assume that the patient and his family can read.

STYE

Also called a hordeolum, a sty is a localized infection that can occur externally (in the lumen of the smaller glands of Zeis or in Moll's glands) or internally (in the larger meibomian gland). A sty can occur in any patient at any age. Generally, the infection responds well to treatment but tends to recur.

Causes

A staphylococcal organism, most commonly *Staphylococcus aureus*, causes a sty.

Complications

If untreated, a sty may lead to cellulitis of the eyelid.

Assessment findings

The patient typically complains of a painful swelling of the eyelid. Inspection of the eyelid may reveal a red, swollen area. At the eyelid margin, you may also observe an abscess that displaces the eyelash, making the eyelash point straight outward from the center of the abscess.

Diagnostic tests

A culture of the purulent material from the abscess usually reveals a staphylococcal organism.

Treatment

Warm compresses applied for 10 to 15 minutes four times daily for 3 to 4 days aid drainage of the abscess. This treatment also relieves pain and inflammation and promotes suppuration.

Drug therapy includes a topical sulfonamide or antibiotic eyedrops or ointment and, occasionally, a systemic antibiotic. If the patient is prone to recurring styes, lid scrubs should be performed daily and antibiotic ointment or drops may be indicated.

If conservative treatment fails, incision and drainage may be necessary.

Nursing diagnoses

- u Altered health maintenance
- u Impaired skin integrity
- u Pain
- u Risk for infection
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient's skin integrity will remain intact.
- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.

Nursing interventions

- u Administer antibiotics as ordered.

- u Apply warm compresses to help drain infection and relieve pain. Use a sterile bowl and gauze and warm tap water.

Patient teaching

- u Instruct the patient to use a clean cloth for each warm compress application and to dispose of it or launder it separately to prevent spreading infection to family members. For the same reason, the patient should avoid sharing towels and washcloths.
- u Caution the patient to avoid squeezing the sty or rubbing the eye; this spreads the infection and may cause cellulitis.
- u Teach the patient or a family member how to instill eyedrops or ointment into the cul-de-sac of the lower eyelid.
- u Warn that ophthalmic ointment may blur vision.
- u Teach proper eye hygiene to prevent recurrent infections.

Disorders of the conjunctiva

Conjunctival disorders typically cause obvious inflammation. Although some are self-limiting, others may lead to blindness if left untreated.

CONJUNCTIVITIS

Whether caused by an allergen, a viral or bacterial infection, or a chemical reaction, conjunctivitis is characterized by hyperemia of the conjunctiva. The disorder is transmitted by contaminated towels, washcloths, or the patient's own hand and usually spreads rapidly from one eye to the other. Commonly benign and self-limiting, it seldom affects vision. Chronic conjunctivitis may signal degenerative changes or damage from repeated acute attacks.

Acute bacterial conjunctivitis—or pinkeye—usually lasts about 2 weeks. Some viral conjunctival infections may last 2 to 3 weeks, whereas others follow a chronic course and may produce severe disability. In the western hemisphere, conjunctivitis is probably the most common eye disorder.

Causes

Among the substances and organisms that cause conjunctivitis are:

- u allergens, such as pollen, grass, cosmetics, topical medications, air pollutants, smoke, and seasonal allergens. Vernal conjunctivitis apparently results from various, unidentified allergens, although it's sometimes associated with grass or pollen sensitivity. This form of conjunctivitis affects both eyes, usually begins before puberty, and may persist intermittently for about 10 years.
- u bacteria, such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Neisseria gonorrhoeae*, and *N. meningitides*
- u chlamydia such as *Chlamydia trachomatis* (which causes inclusion conjunctivitis)
- u viruses, such as herpes simplex virus type 1 and adenovirus types 3, 7, and 8 (type 8 is primarily responsible for epidemic keratoconjunctivitis).

Understanding corneal ulcers

Corneal ulcers in the central or marginal cornea can produce scarring, perforation, and blindness. Treatment within hours of onset can prevent visual impairment.

Corneal ulcers usually result from bacterial, viral, or fungal infections. Other causes include traumatic injury, reactions to toxins and allergens, corneal exposure, tuberculoprotein, vitamin A deficiency, and fifth cranial nerve lesions.

The patient usually reports pain, photophobia, tearing and, sometimes, blurred vision. You may observe eye congestion, purulent discharge, or purulence in the anterior chamber.

Fluorescein dye instilled in the conjunctival sac stains the ulcer's outline and makes it visible. The causative bacterium or fungus may be identified through culture and sensitivity testing of a corneal scraping.

For infection-related ulcers, broad-spectrum antibiotics are used until the cause is identified. Dietary deficiency or GI malabsorption of vitamin A may be corrected. Neurotropic or exposure ulcers require the use of artificial tears, lubricating ointments, or a plastic bubble eye shield. Suturing the eyelids closed may be necessary until the eye heals.

An idiopathic form of conjunctivitis may be associated with certain systemic diseases, such as erythema multiforme, chronic follicular conjunctivitis, and thyroid disease. Conjunctivitis may also be secondary to pneumococcal dacryocystitis or canaliculitis caused by a candidal infection.

Complications

Untreated, allergic conjunctivitis may lead to a tic; epidemic keratoconjunctivitis may result in corneal infiltrates; and herpes simplex conjunctivitis may lead to corneal ulcers and subsequent eye loss. (See [Understanding corneal ulcers](#).)

Assessment findings

The patient may complain of eye pain and sensitivity to light (photophobia). He may also report burning, itching, and the sensation of a foreign body in the eye (which suggests bacterial conjunctivitis). If the patient is a child, he may complain of a sore throat and fever as well.

Inspection typically discloses conjunctival hyperemia, discharge, and tearing. You may also see a crust of sticky, mucopurulent discharge, which indicates bacterial conjunctivitis. Or you may see a profuse, purulent discharge, which indicates gonococcal conjunctivitis. Copious tearing and minimal discharge suggest viral conjunctivitis.

In vernal conjunctivitis, inspection of the conjunctiva of the upper eyelid may reveal bumps, or conjunctival papillae. (See [Conjunctival papillae](#).) Palpation of the preauricular lymph node on the affected side may uncover an enlargement, suggesting viral conjunctivitis.

Diagnostic tests

Stained smears of conjunctival scrapings show mostly monocytes if a virus causes conjunctivitis. Polymorphonuclear cells (neutrophils) predominate if bacteria cause conjunctivitis, and eosinophils predominate if an allergen causes conjunctivitis.

Culture and sensitivity tests may be used to identify a bacterial pathogen and indicate appropriate antibiotic therapy.

Treatment

A patient with bacterial conjunctivitis requires an appropriate topical antibiotic. Although viral conjunctivitis resists treatment, broad-spectrum antibiotic eyedrops may prevent secondary infection. Herpes simplex infection generally responds to trifluridine drops, vidarabine ointment, or oral acyclovir, but the infection may persist for 2 to 3 weeks. Treatment for a patient with vernal conjunctivitis includes instilling corticosteroid drops followed by lodoxamide trometh-amine (Alomide), a

histamine₁-receptor antagonist, cold compresses to relieve itching and, occasionally, oral antihistamines.

Instillation of a one-time dose of tetracycline or erythromycin ointment in the eyes of neonates prevents gonococcal and chlamydial conjunctivitis.

Nursing diagnoses

- u Altered health maintenance
- u Anxiety
- u Risk for infection
- u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will regain visual function.

Nursing interventions

- u Apply warm compresses and therapeutic ointment or eyedrops as ordered. Don't irrigate the eye because this will spread the infection.
- u Notify public health officials if culture results identify *N. gonorrhoeae*.
- u Obtain culture specimens before antibiotic therapy.

Patient teaching

- u Show the patient proper hand-washing techniques. Because some forms of conjunctivitis are highly contagious, urge the patient and family members to avoid sharing washcloths, towels, and pillows.

ALERT Caution the patient against rubbing his infected eye. This can spread the infection to the other eye and to other people. Warn the patient with “cold sores” to avoid kissing others on the eyelids to prevent the spread of the disease.

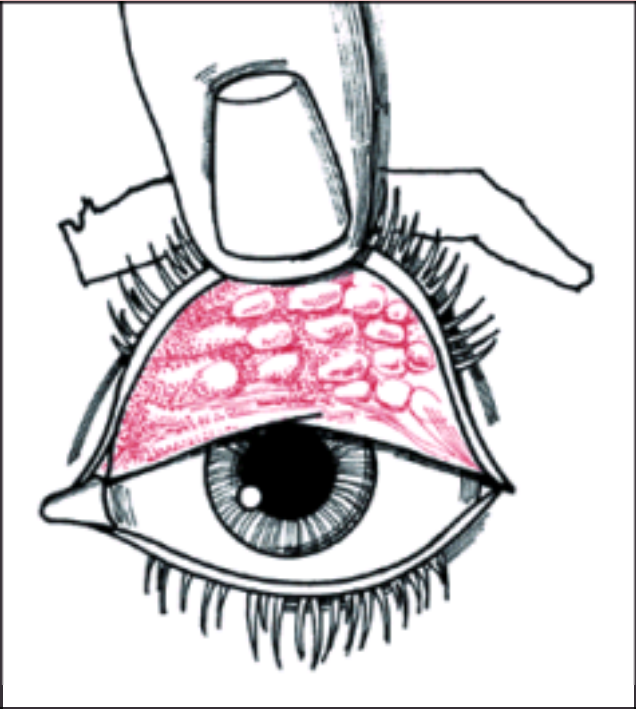

- u Demonstrate how to instill eyedrops and ointments correctly without touching the bottle tip to the eye or eyelashes.
- u Explain the purpose, dosage, and possible adverse effects of drug therapy. Emphasize the importance of completing the prescribed course.
- u If conjunctivitis results from a sexually transmitted organism, such as *N. gonorrhoeae*, review the methods for preventing disease transmission.
- u Stress the importance of wearing safety glasses if the patient works near chemical irritants.

INCLUSION CONJUNCTIVITIS

A fairly common, acute ocular inflammation, inclusion conjunctivitis results from infection by *Chlamydia trachomatis*. Also known as inclusion blennorrhea, the disease develops 5 to 10 days after contamination and may persist for weeks or months. If untreated, it runs a course of 3 to 9 months.

Conjunctival papillae

If you see papillae in the conjunctiva of the upper eyelid, your patient may have vernal (allergic) conjunctivitis. These cobblestone bumps are the telltale sign. They result from swollen lymph tissue within the conjunctival membrane.

Causes and pathophysiology

The microorganism *C. trachomatis* causes inclusion conjunctivitis. This pathogen, which usually infects the urethra in males and the cervix in females, may be transmitted during sexual activity. (Because contaminated cervical secretions can infect the eyes of the neonate during birth, the organism that causes inclusion conjunctivitis may contribute to some cases of ophthalmia neonatorum.) Rarely, inclusion conjunctivitis may result from autoinfection (a person transfers the virus from his genitourinary tract to his own eyes).

Complications

Children and adults may develop otitis media secondary to preauricular lymphadenopathy. In the neonate, pseudomembranes may form, which can lead to conjunctival scarring. Untreated infection can result in blindness.

Assessment findings

In a neonate, note swollen, reddened lower eyelids, excessive tearing, and a moderately purulent discharge. A child or an adult may complain of photosensitivity, which could indicate uveitis. The patient may also report sexual contact with an infected individual. Additionally, you may observe swollen eyelids.

Diagnostic tests

Examination of Giemsa-stained conjunctival scrapings reveals cytoplasmic inclusion bodies in conjunctival epithelial cells and many polymorphonuclear leukocytes. Culture results are usually negative for bacteria.

Treatment

In infants, treatment consists of instilling eyedrops of 1% tetracycline in oil, erythromycin ophthalmic ointment, or sulfonamide eyedrops five or six times daily for 2 weeks. To prevent ophthalmia neonatorum, neonates receive tetracycline or erythromycin ophthalmic ointment as a one-time dose 1 hour after birth.

For adults, treatment calls for administering oral tetracycline or erythromycin for 3 weeks. Severe disease may require concomitant systemic sulfonamide therapy. If the patient has associated uveitis, treatment may include corticosteroids and cycloplegic eyedrops.

Nursing diagnoses

- u Altered health maintenance
- u Pain
- u Risk for infection
- u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain current health status.
- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will regain visual function.

Nursing interventions

- u Keep the patient's eyes clean. Using aseptic technique, clean the eyes from the inner to the outer canthus. Record the amount and color of drainage. Apply warm compresses as needed.
- u If the patient's eyes are sensitive to light, keep the room dark or suggest that he wear dark glasses. Provide appropriate diversional activities.
- u To prevent further spread of inclusion conjunctivitis, wash your hands thoroughly before and after instilling eye medications.

Patient teaching

- u Remind the patient not to rub his eyes, which can irritate them. Teach proper hand-washing techniques and disposal of facial tissues.
- u Inform the patient about his prescribed medication, including its desired actions, dosage, possible adverse effects, and necessary duration of therapy.
- u Review the signs of *C. trachomatis* infections. Discuss ways to prevent infection—for example, with barrier contraceptives.
- u Advise genital examination of any adult with inclusion conjunctivitis or of the mother of an infected neonate.
- u Recommend that the patient alert recent sexual partners to the possibility of chlamydial infection.

Disorders of the cornea

Some corneal disorders, such as abrasions, may be mild and seldom cause complications. Others, such as keratitis, can lead to blindness if untreated.

CORNEAL ABRASION

A scratch on the epithelial surface of the cornea is called a corneal abrasion. With appropriate treatment for this common eye injury, the prognosis is usually good.

Causes

A corneal abrasion usually results from a foreign object, such as a cinder or dirt speck, that becomes embedded under the eyelid. Even if tears wash away the object, the cornea may still sustain injury. Other corneal abrasions can occur in the workplace, especially if a worker doesn't wear safety glasses. Tiny metal fragments may fly into the worker's eyes and quickly rust on the cornea. Similar abrasions commonly affect the eyes of people who fall asleep wearing hard contact lenses.

Complications

A corneal scratch produced by a fingernail, piece of paper, or other organic substance can cause a persistent lesion. If the epithelium doesn't heal properly, recurrent corneal erosion and ulceration may develop, which can lead to permanent vision loss.

Assessment findings

Patient history may include eye trauma or contact lenses worn for a prolonged period. The patient typically reports a sensation of “something in the eye,” sensitivity to light, decreased visual acuity (if the abrasion occurs in the pupillary region), and pain. Discomfort develops because the cornea is richly endowed with nerve endings from the trigeminal nerve (cranial nerve V). This results in pain that is disproportionate to the size of the injury.

Inspection may reveal redness, increased tearing and, possibly, a foreign body on the cornea. Eversion of the eyelid may uncover a foreign object embedded under the eyelid.

Diagnostic tests

After staining with fluorescein, the injured area of the cornea appears green when illuminated by a flashlight. Slit-lamp examination discloses the depth of the abrasion.

Treatment

A deeply embedded foreign body requires removal with a foreign body spud after anesthetizing the cornea with a topical agent. A rust ring on the cornea can be removed with an ophthalmic burr after applying a topical anesthetic. When only partial removal of the rust ring is possible, the eye is left alone to allow reepithelialization, which lifts the rust ring to the surface, allowing complete removal the next day.

Additional treatment includes instilling broad-spectrum antibiotic eyedrops in the affected eye every 3 to 4 hours.

Nursing diagnoses

- u Altered health maintenance
- u Fear
- u Pain
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient and family members will verbalize their feelings and concerns.
- u The patient will express feelings of comfort.
- u The patient will regain visual function.

Nursing interventions

- u Use a flashlight to inspect the patient's cornea. Check his visual acuity before treatment begins. This provides a medical baseline and a legal safeguard.
- u If you see a foreign body in the patient's eye, irrigate the eye with normal saline solution.
- u Administer prescribed antibiotics and cycloplegics as ordered.
- u Instill a topical anesthetic as ordered to ensure comfort and cooperation.

ALERT Never give the patient topical anesthetic drops for self-administration. Abuse of this medication can delay healing, especially if the patient rubs the numb eye and further injures it.

Patient teaching

- u Reassure the patient that the corneal epithelium usually heals in 24 to 48 hours.
- u Teach proper instillation of antibiotic eyedrops as ordered. Explain that an untreated corneal infection can lead to ulceration and permanent vision loss.
- u Emphasize wearing safety glasses in the workplace, if appropriate.
- u If the patient wears contact lenses, review instructions for wear and care to prevent future injury.

KERATITIS

Acute or chronic, keratitis is a corneal inflammation that usually affects only one eye. The inflammation may be deep or superficial. Superficial keratitis is fairly common and may develop at any age. The prognosis depends on the cause.

Causes

Keratitis may result from exposure (such as in Bell's palsy, which prevents the eyelids from closing) or from infection by herpes simplex virus type 1. It may also result from congenital syphilis (interstitial keratitis). Less commonly, it stems from bacterial and fungal infections.

Complications

Untreated, recurrent keratitis may lead to blindness.

Assessment findings

The history may reveal a recent upper respiratory tract infection accompanied by cold sores. The patient with keratitis may complain of eye pain, central vision loss, and sensitivity. He may also report the sensation of a foreign body in his eye. A complaint concerning blurred vision indicates an infection in the center of the cornea.

Inspection may reveal a cornea without its normal luster. If only the lower portion of the cornea is affected, the inflammation may result from exposure.

If keratitis is due to herpes simplex virus type 1 (also known as dendritic keratitis), a characteristic branched lesion of the cornea may be present, resembling the branches of a tree.

Diagnostic tests

Slit-lamp examination of the eye stained with sodium fluorescein may show a portion of the cornea retaining the dye. This indicates that the patient has a corneal inflammation or abrasion. If the fluorescein-stained area shows small branchlike (dendritic) lesions, a herpes simplex virus may cause the keratitis.

Treatment

Acute dendritic keratitis may respond to trifluridine eyedrops or vidarabine ophthalmic ointment, and a broad-spectrum antibiotic may prevent secondary bacterial infection.

Chronic dendritic keratitis may respond more quickly to vidarabine therapy, and long-term topical therapy may be necessary. (Corticosteroid therapy is usually contraindicated in dendritic keratitis or any other viral or fungal disease of the cornea.) For a patient with fungal keratitis, natamycin is the treatment of choice.

Keratitis caused by exposure requires applying a moisturizing ointment and a plastic bubble eye shield or eye patch over the exposed cornea. Treatment for a patient with severe corneal scarring may include keratoplasty (cornea transplantation).

Nursing diagnoses

- u Altered health maintenance
- u Pain
- u Risk for infection
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient will express feelings of comfort.
- u The patient will regain visual function.

Nursing interventions

- u Watch for keratitis in patients predisposed to cold sores.
- u Wear gloves when in contact with the eyes of or ocular drainage from the patient with keratitis from herpes simplex virus.
- u Apply warm compresses to the patient's eye to help relieve pain.
- u Dim the lights if the patient has photophobia.

Patient teaching

- u Review drug action, dosage, instillation techniques, and possible adverse effects.
- u Explain that stress, traumatic injury, fever, colds, and overexposure to the sun can trigger a flare-up of keratitis.
- u Recommend wearing sunglasses to minimize the effects of photophobia.
- u If the keratitis is contagious, teach meticulous hand washing and explain other ways to prevent spreading infection.

Disorders of the uveal tract, retina, and lens

Disorders of the uveal tract, retina, and lens may be acute or chronic and may cause visual disturbances or even vision loss. They include age-related macular degeneration, cataract, retinal detachment, retinitis pigmentosa, uveitis, and vascular retinopathies.

AGE-RELATED MACULAR DEGENERATION

At least 10% of elderly Americans have irreversible central vision loss from age-related macular degeneration. Two primary forms include the atrophic (also called the involutinal or dry) form, which accounts for about 70% of cases, and the exudative (also called the hemorrhagic or wet) form of macular degeneration.

Macular degeneration commonly affects both eyes and is a leading cause of blindness in the United States.

Causes

Age-related macular degeneration results from hardening and obstruction of the retinal arteries, usually associated with age-related degenerative changes. As a result, new blood vessels form (neovascularization) in the macular area and totally obscure central vision. The disorder may also be genetic in origin or may result from an injury, inflammation, or infection.

Complications

Age-related macular degeneration may result in blindness. Bilateral macular lesions may lead to nystagmus.

Assessment findings

The patient may complain of seeing a blank spot in the center of a page (scotoma) while reading. He may tell you that his central vision blurs intermittently and has gradually worsened. He may also report that straight lines appear distorted.

In the patient with dry (nonexudative) macular degeneration, tiny yellowish spots called drusen form beneath the retina. If the drusen are outside the macular area, the patient has no symptoms. If the drusen are within the macula, there is a gradual blurring of vision that is most noticeable when the patient tries to read. With wet (exudative) macular degeneration, symptoms have a rapid onset. The chief complaint is that straight lines appear crooked and that letters appear broken up.

Diagnostic tests

Indirect ophthalmoscopy through a dilated pupil discloses changes in the macular region of the fundus. Fluorescein angiography may identify (in sequential photographs) leaking vessels in the subretinal neovascular net. Amsler grid tests can detect visual distortion (metamorphopsia) on a daily basis, if appropriate.

Treatment

No cure currently exists for the atrophic form of macular degeneration. In patients with the exudative form, argon laser photocoagulation may slow the progression of severe visual loss in 5% to 10% of cases.

Nursing diagnoses

u Fear u Knowledge deficit u Risk for injury u Sensory or perceptual alterations u Social isolation

Key outcomes

- u The patient will express feelings and concerns.
- u The patient won't experience harm or injury.
- u The patient will verbalize an understanding of the condition and treatment.
- u The patient will maintain visual function or will adapt as necessary.

Nursing interventions

- u Help the patient obtain optical aids, such as magnifiers and special lamps, for poor vision.
- u Offer emotional support, and encourage the patient to express fears and concerns.

Patient teaching

- u Point out ways to modify the patient's home environment for safety.
- u Explain that macular degeneration usually doesn't affect peripheral vision, which should be adequate for performing routine activities.
- u If the patient likes to read, refer him to an agency such as the American Foundation for the Blind or Associated Services for the Blind. Agencies like these offer classes in braille and reading alternatives, such as books and other materials on audiocassettes.

CATARACT

Cataract—a common cause of gradual vision loss—is opacity of the lens or the lens capsule of the eye. The clouded lens blocks light shining through the cornea. This, in turn, blurs the image cast onto the retina. As a result, the brain interprets a hazy image.

Cataracts commonly affect both eyes, but each cataract progresses independently. Exceptions are traumatic cataracts, which are usually unilateral, and congenital cataracts, which may remain stationary. Cataracts are most prevalent in people over age 70. Surgery restores vision in about 95% of patients.

Causes

Cataracts are classified by their causes:

- u *Senile cataracts* develop in elderly people, probably because of chemical changes in lens proteins.
- u *Congenital cataracts* occur in neonates from inborn errors of metabolism or from maternal rubella infection during the first trimester; these cataracts may also result from a congenital anomaly or from genetic causes. Transmission is usually autosomal dominant; however, recessive cataracts may be sex-linked.
- u *Traumatic cataracts* develop after a foreign body injures the lens with sufficient force to allow aqueous or vitreous humor to enter the lens capsule.
- u *Complicated cataracts* occur secondary to uveitis, glaucoma, retinitis pigmentosa, or retinal detachment. They can also occur with systemic disease, such as diabetes, hypoparathyroidism, or atopic dermatitis or from ionizing radiation or infrared rays.
- u *Toxic cataracts* result from drug or chemical toxicity with ergot, dinitrophenol, naphthalene, and phenothiazines.

Complications

Without surgery, a cataract eventually causes complete vision loss.

Assessment findings

Typically, the patient complains of painless, gradual vision loss. He may also report a blinding glare from headlights when he drives at night, poor reading vision, and an annoying glare and poor vision in bright sunlight. If he has a central opacity, the patient may report seeing better in dim light than in bright light. That is because

this cataract is nuclear and, as the pupil dilates, the patient can see around the opacity.

Inspection with a penlight may reveal a milky white pupil and, with an advanced cataract, a grayish white area behind the pupil. As the cataract matures, the red reflex is lost.

Diagnostic tests

Indirect ophthalmoscopy reveals a dark area in the normally homogeneous red reflex. Slit-lamp examination is used to confirm the diagnosis of lens opacity and a visual acuity test is used to establish the degree of vision loss.

Treatment

Surgical lens extraction and implantation of an intraocular lens (IOL) to correct the visual deficit is the treatment for a patient with cataract. The surgery is usually performed as a same-day, or outpatient, procedure.

Surgical procedures include the following:

- *Extracapsular cataract extraction*, the most common procedure, involves removing the anterior lens capsule and cortex and leaving the posterior capsule intact. In this procedure, the surgeon implants a posterior chamber IOL where the patient's own lens used to be. This procedure is used for patients of all ages.
- *Intracapsular cataract extraction* involves removing the entire lens within the intact capsule by cryoextraction (the moist lens sticks to an extremely cold metal probe for easy and safe removal with gentle traction). After the surgeon removes the lens, he implants an IOL in either the anterior or posterior chamber. If the patient doesn't receive an IOL, he'll use contact lenses or aphakic glasses to correct vision.
- *Phacoemulsification* relies on ultrasonic vibrations to fragment the lens. The broken pieces are removed by aspiration.

Possible complications of surgery include loss of vitreous (during surgery), wound dehiscence from loosening of sutures and flat anterior chamber or iris prolapse into the wound, hyphema, pupillary block glaucoma, retinal detachment, and infection. In addition, a patient with an IOL implant may experience improved vision almost immediately; however, the IOL corrects distance vision only. The patient also needs either corrective reading glasses or a corrective contact lens, which can be fitted 4 to 8 weeks after surgery.

If the patient didn't receive an IOL, he may receive temporary aphakic cataract glasses. Then, sometime between 4 and 8 weeks after surgery, he has a refraction examination for permanent glasses.

Some patients who have an extracapsular cataract extraction develop a secondary membrane in the posterior lens capsule (which has been left intact), causing decreased visual acuity. This membrane can be removed by the Nd:YAG laser, which cuts an area from the membrane center, thus restoring vision. However, laser surgery alone can't remove a cataract.

Nursing diagnoses

- Anxiety
- Knowledge deficit
- Risk for infection
- Risk for injury
- Sensory or perceptual alterations

Key outcomes

- The patient will maintain current health status.
- The patient won't experience harm or injury.
- The patient and family members will voice their feelings and concerns.
- The patient will regain visual function.

Nursing interventions

- Postoperatively, monitor the patient until he recovers from the effects of the anesthetic. Keep the side rails of the bed up, monitor vital signs, and assist him with early ambulation.
- Apply an eye shield or eye patch postoperatively as ordered.

Patient teaching

- Because the patient will be discharged after he recovers from the anesthetic, remind him to return for a checkup the next day. Caution him to avoid activities that increase intraocular pressure, such as straining with coughing, bowel movements, or lifting.
- Advise the patient to abstain from sex until he receives his doctor's approval.
- Teach the patient or family member how to instill ophthalmic ointment or drops.
- If the patient has increased eye discharge, sharp eye pain (unrelieved by analgesics), or deterioration in vision, instruct him to notify the doctor immediately.

RETINAL DETACHMENT

In retinal detachment, separation of the retinal layers creates a subretinal space that fills with fluid. Twice as common in men as in women, retinal detachment may be primary or secondary. The disorder usually involves only one eye but may occur in the other eye later. A detached retina rarely heals spontaneously; it can usually be reattached successfully with surgery. The prognosis depends on the area of the retina affected.

Causes and pathophysiology

A retinal detachment may be primary or secondary. A *primary detachment* occurs spontaneously because of a change in the retina or the vitreous; a *secondary detachment* results from another problem, such as intraocular inflammation or trauma. The most common cause of retinal detachment is a hole or tear in the retina. This hole allows the liquid vitreous to seep between the retinal layers and separate the sensory retinal layer from its choroidal blood supply. In adults, retinal detachment usually results from degenerative changes related to aging (which cause a spontaneous tear). Predisposing factors include myopia, cataract surgery, and trauma.

Additionally, retinal detachment may result from fluid seeping into the subretinal space as an effect of inflammation, tumors, or systemic disease. (See [Understanding retinal detachment](#).) Or detachment may result from traction placed on the retina by vitreous bands or membranes (resulting from proliferative diabetic retinopathy, posterior uveitis, or a traumatic intraocular foreign body, for example).

The disorder may occasionally develop in a child from retinopathy of prematurity, tumors (retinoblastomas), or trauma. Retinal detachment can also be inherited, usually in association with myopia.

Complications

Retinal detachment may result in severe vision impairment and possible blindness. The patient with spontaneous retinal detachment has a 20% to 25% risk of future retinal detachment in the other eye.

Assessment findings

Initially, the patient may complain that he sees floating spots and recurrent light flashes. As detachment progresses, he may report gradual, painless vision loss described as looking through a veil, curtain, or cobweb. He may relate that the “veil” obscures objects in a particular visual field.

Diagnostic tests

Direct ophthalmoscopy, after full pupil dilation, shows folds or discoloration in the usually transparent retina; indirect ophthalmoscopy can be used to detect retinal tears.

Ocular ultrasonography may be performed to examine the retina if the patient has an opaque lens.

Treatment

Depending on the location and severity of the detachment, treatment may include restricting eye movements to prevent further separation until surgical repair can be made. The patient's head is positioned to allow gravity to pull the detached retina into closer contact with the choroid.

A patient with a hole in the peripheral retina may be treated with cryotherapy. A hole in the posterior retina may respond to laser therapy.

To reattach the retina, scleral buckling may be performed. In this procedure, the surgeon places a silicone plate or sponge over the reattachment site and secures it in place with an encircling band. The pressure exerted gently pushes the choroid and retina together. Scleral buckling may be followed by replacement of the vitreous with silicone, oil, air, or gas.

Nursing diagnoses

u Altered health maintenance u Altered tissue perfusion (retinal) u Anxiety u Impaired tissue integrity u Risk for infection u Sensory or perceptual alterations

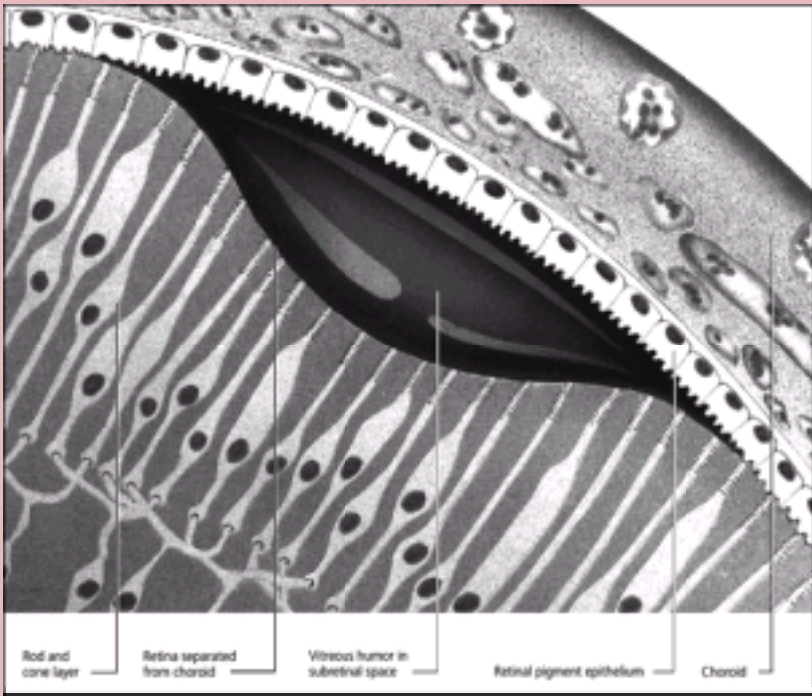

PATHOPHYSIOLOGY

Understanding retinal detachment

Traumatic injury or degenerative changes cause retinal detachment by allowing the retina's sensory tissue layers to separate from the retinal pigment epithelium. This permits fluid—for example, from the vitreous—to seep into the space between the retinal pigment epithelium and the rods and cones of the tissue layers.

The pressure, which results from the fluid entering the space, balloons the retina into the vitreous cavity away from choroidal circulation. Separated from its blood supply, the retina can't function. Without prompt repair, the detached retina can cause permanent vision loss.

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient and family members will voice their feelings and concerns.
- u The patient will regain visual function.

Nursing interventions

- u Provide encouragement and emotional support to decrease anxiety caused by vision loss.
- u Prepare the patient for surgery by cleaning the face with a mild (no-tears) shampoo. Give antibiotics and cycloplegic or mydriatic eyedrops as ordered.
- u In macular involvement, keep the patient on bed rest (with or without bathroom privileges) to prevent further retinal detachment.
- u Postoperatively, position the patient as directed (the position varies according to the surgical procedure). To prevent increasing intraocular pressure (IOP), administer antiemetics as indicated. Discourage any activities that could increase IOP.
- u Observe for slight localized corneal edema and peri-limbal congestion, which may follow laser therapy. To reduce edema and discomfort, apply ice packs and administer acetaminophen as ordered for headache.
- u If the patient receives a retrobulbar injection, apply a protective eye patch because the eyelid remains partially open.
- u After removing the protective patch, give cycloplegic and steroidal or antibiotic eyedrops as ordered. Apply cold compresses to decrease swelling and pain, but avoid putting pressure on the eye.
- u Give analgesics as needed, and report persistent pain.

Patient teaching

- u Encourage leg and deep-breathing exercises to prevent complications of immobility.
- u Explain to the patient undergoing laser therapy that the procedure may be done in same-day surgery. Forewarn him that he may have blurred vision for several days afterward.
- u Instruct the patient to rest and to avoid driving, bending, heavy lifting, or any other activities that affect IOP for several days after eye surgery. Discourage activities that could cause the patient to bump the eye.
- u Show the patient having scleral buckling surgery how to instill eyedrops properly. After surgery, remind him to lie in the position recommended by the doctor.
- u Advise the patient to wear sunglasses if photosensitivity occurs.
- u Instruct the patient to take acetaminophen as needed for headaches and to apply ice packs to the eye to reduce swelling and alleviate discomfort.

- u Review the signs of increasing IOP and infection, emphasizing those that require immediate attention.
- u Review early symptoms of retinal detachment and emphasize the need for immediate treatment.

RETINITIS PIGMENTOSA

Retinitis pigmentosa is a genetically transmitted, progressive destruction of the retinal rods that results in atrophy of the retinal pigment epithelium and eventual blindness. As degeneration progresses from the rods to the cones, central vision loss occurs.

Retinitis pigmentosa commonly accompanies other hereditary disorders in several distinct syndromes, most commonly the Laurence-Moon-Biedl syndrome, typified by visual destruction (from retinitis pigmentosa), obesity, mental retardation, polydactyly, and hypogonadism.

Causes

About 80% of children with retinitis pigmentosa inherit it as an autosomal recessive trait. The genetic defect causes production of an unstable form of rhodopsin, the receptor protein of rod cells in the retina. Onset occurs before age 20, initially affecting night and peripheral vision. The disease progresses inevitably—sometimes rapidly—to blindness before age 50. Retinitis pigmentosa may also be transmitted as an X-linked trait, which leads to the least common but most severe form of the disease and usually causes blindness before age 40.

Complications

Retinitis pigmentosa ultimately results in total blindness.

Assessment findings

Patient history may include additional eye disorders, such as cataracts, choroidal sclerosis, macular degeneration, glaucoma, keratoconus, or scotoma (blind spots). The patient's family history may include other members with retinitis pigmentosa.

The patient generally complains of night blindness beginning in his teenage years. As the disease progresses, he typically reports a gradually narrowing visual field described as tunnel or “gun-barrel” vision. Blindness ultimately results.

Diagnostic tests

Electroretinography shows an absent or slower than normal retinal response time. Visual field testing (using a tangent screen) is used to detect ring scotoma.

Ophthalmoscopy may initially disclose a normal fundus and later show characteristic black pigmentary disturbances. Electrophysiologic examination (electroretinogram) is used to test the function of the rods and cones and is helpful in evaluating the extent of the disease.

Treatment

Although extensive research continues, no cure exists for retinitis pigmentosa.

Nursing diagnoses

- u Altered health maintenance u Body image disturbance u Dysfunctional grieving u Fear u Knowledge deficit u Powerlessness u Risk for injury u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain current health status.
- u The patient and family members will express their feelings and concerns.
- u The patient won't experience harm or injury.
- u The patient and family members will express an understanding of the condition and treatment.

Nursing interventions

- u Allow the patient to express his feelings about impending blindness. Offer emotional support, and refer the patient to an appropriate clinical specialist as necessary.
- u Accept the patient's perception of self. Assess his readiness for decision making. Then, as appropriate, involve him in making choices and decisions related to his care.
- u Encourage participation in self-care. Provide reinforcement for the patient's positive efforts and activities.

Patient teaching

- u Teach the patient and family members about retinitis pigmentosa. Explain that it's hereditary, and suggest genetic counseling for adults who risk transmitting it to future offspring.
- u Point out ways of modifying the environment for safety. Orient the patient to the layout of the room and the location of the furniture. Tell the patient's family to keep walkways clear of obstruction.
- u Forewarn the patient about driving a car at night, explaining that poor vision eventually impedes safety. If appropriate, provide information about special eyeglasses that may help patients with retinitis pigmentosa see at night. (Such lenses are expensive.)
- u Refer the patient to a social service agency or to the National Retinitis Pigmentosa Foundation for additional information and counseling.

UVEITIS

An inflammation of one uveal tract, uveitis may occur as anterior uveitis, which affects the iris (iritis) or the iris and the ciliary body (iridocyclitis); posterior uveitis, which affects the choroid (choroiditis) or the choroid and the retina (chorioretinitis); or panuveitis, which affects the entire uveal tract.

Although clinical distinction isn't always possible, anterior uveitis occurs in two forms—granulomatous and nongranulomatous. Previously, granulomatous uveitis was thought to result from tuberculosis bacilli; nongranulomatous uveitis, from streptococci. Although it's now known that these pathogens do not cause the disease forms, the names remain in use. The onset of anterior uveitis may be acute or insidious. Posterior uveitis begins insidiously and may be acute or chronic.

Causes

Uveitis is typically an idiopathic inflammation that can result from allergy, bacteria, viruses, fungi, chemicals, trauma, surgery, or systemic diseases, such as rheumatoid arthritis and ankylosing spondylitis.

Complications

If severe, a hypopyon (accumulation of pus in the anterior chamber) can occur. Untreated, anterior uveitis progresses to posterior uveitis, which may lead to scarring,

cataracts, glaucoma, or retinal detachment. Posterior uveitis usually produces some residual vision loss and markedly blurred vision.

Assessment findings

The patient with anterior uveitis may complain of a dull ache in one eye, blurred vision, and sensitivity to light. With posterior uveitis, he may report slightly blurred vision or floating spots.

Inspection of the external eye may disclose severe ciliary congestion, tearing, and a small pupil that doesn't react to light. Iris color may change.

Diagnostic tests

Slit-lamp examination findings in both anterior and posterior uveitis reveal milkiness of the aqueous humor and inflammatory cell particles on the back of the cornea. This pattern resembles light passing through smoke. With a special lens, slit-lamp examination and ophthalmoscopy can also identify active inflammatory fundal lesions involving the retina, the choroid, or both.

Serologic tests can detect toxoplasmosis as the cause of posterior uveitis.

Treatment

Uveitis requires vigorous and prompt management, which includes treatment for any known underlying cause and application of a topical cycloplegic, such as 1% atropine sulfate. Additional therapy may involve applying topical and subconjunctival corticosteroids.

For severe uveitis, the patient may receive oral systemic corticosteroids. Because long-term corticosteroid therapy can increase intraocular pressure (IOP) and cause cataracts, the patient will need IOP monitoring during the active inflammatory stage. If IOP increases, therapy includes an antiglaucoma drug, such as the beta-adrenergic blocker timolol, or acetazolamide, a carbonic anhydrase inhibitor.

Nursing diagnoses

- u Altered health maintenance
- u Anxiety
- u Pain
- u Risk for infection
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient will express feelings of comfort.
- u The patient will regain visual function.

Nursing interventions

- u Encourage rest during the acute phase of uveitis.
- u Administer prescribed drugs, including analgesics.

Patient teaching

- u Teach the patient how to instill eyedrops.
- u Explain the purpose, dosage, and adverse effects of the prescribed drug. Instruct the patient to report adverse effects of systemic corticosteroids, such as edema and weakness.
- u Suggest wearing sunglasses to relieve photophobia.
- u Urge the patient to seek follow-up care because of the strong likelihood of recurrence. Instruct him to seek treatment at the first sign of uveitis.

VASCULAR RETINOPATHIES

An interruption in blood supply to the eye can produce a vascular retinopathy, which is a noninflammatory retinal disorder. Common vascular retinopathies include central retinal artery occlusion, central retinal vein occlusion, diabetic retinopathy, and hypertensive retinopathy.

Central retinal artery occlusion occurs unilaterally and affects elderly patients. The prognosis is poor—in 5% to 20% of patients, secondary glaucoma develops rapidly 3 to 4 months after occlusion.

Central retinal vein occlusion, most prevalent in elderly patients, causes vision loss more slowly than central retinal artery occlusion.

Diabetic retinopathy is the leading cause of blindness among people ages 20 to 44. About 40% of patients who have had type I diabetes and about 25% of those who have had type II diabetes for 10 years develop retinopathy. After 15 years, the disorder develops in about 95% of people with type I diabetes and in about 50% of those with type II diabetes. At additional risk are pregnant patients, blacks (who have a 20% greater risk than whites), and women (who have a 23% greater risk than men).

Causes and pathophysiology

When a retinal vessel becomes obstructed, the diminished blood flow causes visual deficits. *Central retinal artery occlusion* may be idiopathic or may result from embolism, atherosclerosis, infection, or conditions that retard blood flow, such as temporal arteritis, carotid occlusion, and heart failure.

Central retinal vein occlusion may result from external compression of the retinal vein, trauma, diabetes, thrombosis, granulomatous diseases, generalized and localized infections, glaucoma, and atherosclerosis.

Diabetic retinopathy results from diabetes, which causes microcirculatory changes. These changes occur more rapidly when diabetes is poorly controlled. (See [Progression of diabetic retinopathy](#).)

Hypertensive retinopathy results from prolonged hypertension, which produces retinal vasospasm and consequent damage to and narrowing of the arteriolar lumen.

PATHOPHYSIOLOGY

Progression of diabetic retinopathy

The patient with diabetic retinopathy needs careful vision monitoring because the disorder can accelerate without warning, progressing from a nonproliferative condition to a proliferative disease.

Nonproliferative diabetic retinopathy

Initially, the retinal blood vessel linings undergo changes. These changes cause the vessels to leak plasma or fatty substances that decrease or block blood flow (nonperfusion) within the retina. Diabetic retinopathy may also produce microaneurysms and small hemorrhages.

Proliferative diabetic retinopathy

Later, in a process called neovascularization, fragile new blood vessels form and proliferate on the optic disk and elsewhere on the fundus. These vessels can grow into the vitreous and then rupture, causing vitreous hemorrhage and subsequent blindness. Also, scar tissue may form along the new blood vessels and pull on the retina, causing macular distortion and possible retinal detachment.

Complications

In many patients, central retinal artery occlusion causes permanent blindness. Central retinal vein occlusion may result in secondary glaucoma. Diabetic retinopathy may end in blindness or cranial nerve neuropathy. Hypertensive retinopathy may also lead to blindness.

Assessment findings

The patient with central retinal artery occlusion may complain of transient vision loss in one eye. The episode may last from a few seconds to 10 minutes. As the disorder progresses, however, the patient may report sudden, painless, partial or complete vision loss in the eye. *(Note:* Although this condition typically causes permanent blindness, some patients experience spontaneous resolution within hours and regain partial vision.) If central retinal artery occlusion results in secondary neurovascular glaucoma (uncontrolled proliferation of weak blood vessels), the patient typically complains of eye pain.

In central retinal vein occlusion, the patient usually complains of diminished visual acuity. He may only perceive hand movements and light.

Some patients with diabetic retinopathy may report no symptoms. Complaints in hypertensive retinopathy depend on the location of retinopathy. For example, retinopathy near the macula may cause only blurred vision. Patients with prolonged severe disease may report headaches and severe vision loss—even blindness. In the pregnant patient, hypertensive retinopathy may occur with eclampsia.

Diagnostic tests

Appropriate tests depend on the type of vascular retinopathy. Evaluation needs to include visual acuity findings and ophthalmoscopic examination. (See [Diagnostic tests in vascular retinopathies.](#))

Treatment

No particular treatment is known to control central retinal artery occlusion. However, an attempt is made to release the occlusive plaque or emboli into the peripheral retinal circulation. To reduce intraocular pressure, therapy includes acetazolamide 500 mg I.V., eyeball massage with a Goldman-type gonioscopes and, possibly, anterior chamber paracentesis. Therapy also includes inhalation of carbogen (95% oxygen and 5% carbon dioxide) to improve retinal oxygenation. Because inhalation therapy may be given hourly for up to 48 hours, the patient requires hospitalization for close monitoring of vital signs.

Therapy for central retinal vein occlusion may include aspirin, which acts as a mild anticoagulant. Laser photocoagulation may reduce the risk of neovascular glaucoma for some patients whose eyes have widespread capillary nonperfusion.

Treatment for patients with early-stage, nonproliferative diabetic retinopathy is prophylactic. Careful control of the patient's blood glucose levels during the first 5 years of diabetes may decrease the severity of retinopathy or delay its onset. For the patient with microaneurysms, therapy should include frequent eye examinations (three or four times yearly) to monitor the condition. For a child with diabetes, therapy should include an annual eye examination by an ophthalmologist.

The treatment choice for patients with proliferative diabetic retinopathy is laser photocoagulation. This process involves cauterizing the weak, leaking blood vessels. Laser treatment may be focal (aimed directly at new blood vessels) or panretinal (placing as many as 2,000 burns throughout the peripheral retina). Despite such treatment, neovascularization doesn't always regress, and vitreous hemorrhage, with or without retinal detachment, may follow. If the leaked blood isn't absorbed in 3 to 6 months, vitrectomy may be performed to restore partial vision.

Treatment for patients with hypertensive retinopathy includes controlling blood pressure with appropriate drugs, diet, and exercise. Adherence to this regimen typically resolves ocular signs and symptoms.

ADVANCED PRACTICE

Diagnostic tests in vascular retinopathies

In vascular retinopathies, diagnostic tests vary depending on the type of retinopathy, such as central retinal artery occlusion, central retinal vein occlusion, diabetic retinopathy, or hypertensive retinopathy.

Central retinal artery occlusion

- u *Ophthalmoscopy* (direct or indirect) shows emptying of retinal arterioles.
- u *Slit-lamp examination*: within 2 hours of occlusion reveals clumps or segmentation in the artery. Later examination shows a milky white retina around the optic disk (resulting from swelling and necrosis of ganglion cells caused by reduced blood supply). Other findings include a cherry-red spot in the macula. (This spot subsides after several weeks.)
- u *Ophthalmodynamometry* is used to measure approximate relative pressures in the central retinal arteries and indirectly assess internal carotid artery blockage.
- u *Ultrasonography* reveals blood vessel conditions in the neck.
- u *Digital subtraction angiography* is used to evaluate carotid occlusion with no need for arteriography.
- u *Magnetic resonance imaging* displays the cause of obstruction.
- u *Contrast-enhanced computed tomography scanning* discloses the diseased carotid artery.
- u *Electrophysiologic examinations* (electroretinogram, electrooculogram, dark adaptometry, visual evoked potential) are used to assess the function of the visual pathway from the photoreceptors in the retina to the visual cortex of the brain.

Central retinal vein occlusion

- u *Ophthalmoscopy* (*direct or indirect*) reveals retinal hemorrhage, retinal vein engorgement, white patches among hemorrhages, and edema around the optic disk.
- u *Ultrasonography* can confirm or rule out occluded blood vessels.

Diabetic retinopathy

- u *Slit-lamp examination*: shows thickening of retinal capillary walls.
- u *Indirect ophthalmoscopy* demonstrates retinal changes, such as microaneurysms (earliest change), retinal hemorrhages and edema, venous dilation and beading, exudates, vitreous hemorrhage, proliferation of fibrin into vitreous from retinal holes, growth of new blood vessels, and microinfarctions of the nerve fiber layer.
- u *Fluorescein angiography* highlights leakage of fluorescein from dilated vessels and is used to differentiate between microaneurysms and true hemorrhages.

Hypertensive retinopathy

- u *Ophthalmoscopy* (*direct or indirect*) performed in early disease discloses hard and shiny deposits, tiny hemorrhages, narrowed arterioles, nicking of the veins where arteries cross them (referred to as arteriovenous nicking), and elevated arterial blood pressure.

The same test done later in the disease process shows cotton wool patches, exudates, retinal edema, papilledema caused by ischemia and capillary insufficiency, hemorrhages, and microaneurysms.

Nursing diagnoses

- u Altered health maintenance
- u Anxiety
- u Fear
- u Impaired tissue integrity
- u Knowledge deficit
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will maintain current health status.
- u The patient won't experience harm or injury.
- u The patient and family members will voice their feelings and concerns.
- u The patient will regain visual function.
- u The patient and family members will express an understanding of the condition and treatment.

Nursing interventions

- u Arrange for immediate ophthalmologic evaluation when a patient complains of sudden vision loss. Blindness may be permanent if treatment is delayed.
- u Encourage the patient to express his fears about vision loss.
- u Monitor the patient's blood pressure if he complains of occipital headache and blurred vision.
- u Administer acetazolamide I.V. as ordered. During inhalation therapy, monitor vital signs before and after treatment. Continue this therapy if the patient's blood pressure fluctuates markedly, if an arrhythmia develops, or if the patient becomes disoriented.

Patient teaching

- u Urge the patient with hypertensive retinopathy to comply with antihypertensive therapy and to have regular blood pressure checks.
- u Teach the diabetic patient about care procedures as necessary. Explain home glucose monitoring, insulin therapy, dietary modifications, and exercise regimens. Urge the patient to comply with the prescribed regimen. Encourage regular eye examinations.
- u Teach the patient to report any new visual symptoms, such as blurred vision, floaters, cobwebs, or flashing lights.
- u Review ways to modify the environment for safety, especially if the patient has vision loss.

Miscellaneous disorders

Miscellaneous disorders include extraocular motor nerve palsies, glaucoma, and strabismus.

EXTRAOCULAR MOTOR NERVE PALSIES

In extraocular motor nerve palsies, dysfunction affects the third, fourth, and sixth cranial nerves. These nerves are responsible for innervating eye movement. The superior branch of the oculomotor (cranial III) nerve innervates the levator superioris muscle of the upper eyelid and the superior rectus muscle of the eye; the inferior branch innervates the interior rectus, the medial rectus, and the inferior oblique muscles. It also supplies the intrinsic pupillary and ciliary body muscles, which control lens shape and accommodation. The trochlear (cranial IV) nerve innervates the superior oblique muscles, which control downward rotation, intorsion, and abduction of the eye. The abducens (cranial VI) nerve innervates the lateral rectus muscles, which control inward movement of the eye.

Causes

The most common causes of extraocular motor nerve palsies include diabetic neuropathy, trauma, and pressure from an aneurysm or a brain tumor. Other causes vary depending on the cranial nerve involved.

Oculomotor (third nerve) palsy, or acute ophthalmoplegia, also results from brain stem ischemia or other cerebrovascular disorders, poisoning (lead, carbon monoxide, botulism), alcohol abuse, infections (measles, encephalitis), trauma to the extraocular muscles, myasthenia gravis, or tumors in the cavernous sinus area.

Trochlear (fourth nerve) palsy also may result from closed-head trauma (for example, a blowout fracture) or sinus surgery.

Abducens (sixth nerve) palsy also results from increased intracranial pressure, brain abscess, cerebrovascular accident, meningitis, arterial brain occlusion, infections of the petrous bone (rare), lateral sinus thrombosis, myasthenia gravis, and thyrotropic exophthalmos.

Complications

In extraocular motor nerve palsies, problems that accompany the disease include diplopia, ptosis, strabismus, nystagmus, and ocular torticollis.

Assessment findings

The patient characteristically reports recent onset of diplopia, which varies in different fields of gaze depending on the eye muscles affected. Additionally, the patient with fourth or sixth nerve palsy may complain of torticollis (wry neck) from repeatedly turning his head to compensate for visual field deficits.

If the patient has third nerve palsy, inspection may disclose ptosis, exotropia (eye positioned outward), pupillary dilation, and unresponsiveness to light and accommodation. The patient can't move the eye.

If the patient has fourth nerve palsy, you may observe that he can't rotate his eye downward or upward. The patient with sixth nerve palsy may have esotropia (inward deviation of the eye).

Diagnostic tests

A patient with extraocular motor nerve palsy needs to supply a full health history and undergo a complete neuroophthalmologic examination before diagnosis is confirmed. Differential diagnosis of third, fourth, or sixth nerve palsy depends on the specific motor defect exhibited by the patient.

Depending on the patient's symptoms, blood studies may be ordered to detect diabetes; computed tomography scanning, magnetic resonance imaging, or skull X-rays make be taken to rule out intracranial tumors; and cerebral angiography may be used to evaluate possible vascular abnormalities such as aneurysm.

If sixth nerve palsy results from an infection, culture and sensitivity tests may be used to identify the causative organism and determine therapy.

Treatment

Appropriate treatment varies depending on the cause. For instance, neurosurgery may be necessary for a brain tumor or an aneurysm. For infection, massive doses of I.V. antibiotics may be appropriate. After treatment for the primary condition, the patient may need to perform exercises that stretch the neck muscles to correct acquired torticollis. Other care and treatments depend on residual symptoms.

Nursing diagnoses

- u Anxiety
- u Body image disturbance
- u Fear
- u Knowledge deficit
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will express feelings and concerns.
- u The patient won't experience harm or injury.
- u The patient and family members will express an understanding of the condition and treatment.
- u The patient will regain visual function.

Nursing interventions

- u Provide emotional support to help minimize the patient's anxiety about the cause of motor nerve palsy.

Patient teaching

- u Show the patient with acquired torticollis how to perform neck-stretching and range-of-motion exercises.
- u Teach the patient to be alert for factors that may contribute to injury. For example, the patient with diplopia lacks depth perception; instruct him to navigate stairs cautiously.

GLAUCOMA

Glaucoma is a group of disorders characterized by high intraocular pressure (IOP) that damages the optic nerve. Glaucoma may occur as a primary or congenital disease or secondary to other causes, such as injury, infection, surgery, or prolonged topical corticosteroid use.

Primary glaucoma has two forms: open-angle (also known as chronic, simple, or wide-angle glaucoma) and angle-closure (also known as acute or narrow-angle) glaucoma. Angle-closure glaucoma attacks suddenly and may cause permanent vision loss in 48 to 72 hours.

Glaucoma—one of the leading causes of blindness—affects about 2% of Americans over age 40 and accounts for about 12% of newly diagnosed blindness in the United States. The incidence is highest among males and African-American and Asian populations. In the United States, early detection and effective treatment contribute to the good prognosis for preserving vision.

Causes and pathophysiology

Open-angle glaucoma results from degenerative changes in the trabecular meshwork. These changes block the flow of aqueous humor from the eye, which causes IOP to increase. The result is optic nerve damage. Open-angle glaucoma affects about 90% of all patients who have glaucoma and commonly occurs in families.

Angle-closure glaucoma results from obstruction to the outflow of aqueous humor caused by an anatomically narrow angle between the iris and the cornea. This causes IOP to increase suddenly. Angle-closure glaucoma attacks may be triggered by trauma, pupillary dilation, stress, or any ocular change that pushes the iris forward (for example, a hemorrhage or swollen lens).

Secondary glaucoma can proceed from such conditions as uveitis, trauma, drug use (such as corticosteroids), venous occlusion, or diabetes. In some instances, new blood vessels (neovascularization) form, blocking the passage of aqueous humor.

Complications

If untreated, glaucoma can progress from gradual vision loss to total blindness.

Assessment findings

Because open-angle glaucoma begins insidiously and progresses slowly, the patient may have no symptoms. Later, he may complain of a dull, morning headache; mild aching in the eyes; loss of peripheral vision; seeing halos around lights; and reduced visual acuity (especially at night) that is uncorrected by glasses.

Angle-closure glaucoma typically has a rapid onset and is an emergency. The patient may complain of pain and pressure over the eye, blurred vision, decreased visual acuity, seeing halos around lights, and nausea and vomiting (from increased IOP).

Inspection may reveal unilateral eye inflammation, a cloudy cornea, and a moderately dilated pupil that is nonreactive to light. Palpation may also disclose increased IOP discovered by applying gentle fingertip pressure to the patient's closed eyelids. With angle-closure glaucoma, one eye may feel harder than the other.

Diagnostic tests

Tonometry (with an applanation, Schiøtz, or pneumatic tonometer) is used to measure IOP and provide a baseline for reference. Normal IOP ranges from 8 to 21 mm Hg. However, patients whose pressures fall within the normal range can develop signs and symptoms of glaucoma, and patients who have abnormally high pressure may have no clinical effects.

Slit-lamp examination allows the examiner to see the effects of glaucoma on the anterior eye structures, including the cornea, iris, and lens.

Gonioscopy is used to determine the angle of the eye's anterior chamber. This enables the examiner to distinguish between open-angle and angle-closure glaucoma. The angle is normal in open-angle glaucoma. In older patients, however, partial closure of the angle may occur (allowing two forms of glaucoma to coexist).

Ophthalmoscopy facilitates visualization of the fundus. In open-angle glaucoma, cupping of the optic disk may be seen earlier than in angle-closure glaucoma. Perimetry or visual field tests are used to determine the extent of peripheral vision loss, which helps to evaluate deterioration in open-angle glaucoma. Fundus photography is used to monitor and record optic disk changes.

Treatment

For a patient with open-angle glaucoma, the initial goal of treatment is to reduce pressure by decreasing aqueous humor production with medications. These include beta-adrenergic blockers, such as timolol (used cautiously in asthmatics or patients with bradycardia) or betaxolol. Other drug treatments include epinephrine to dilate the pupil (contraindicated in angle-closure glaucoma) and miotic eyedrops, such as pilocarpine, to promote aqueous humor outflow.

Patients who don't respond to drug therapy may benefit from argon laser trabeculoplasty or from a surgical filtering procedure called trabeculectomy. This procedure involves creating an opening for outflowing aqueous humor.

To perform *argon laser trabeculoplasty*, the ophthalmologist focuses an argon laser beam on the trabecular meshwork of an open angle. This produces a thermal burn that changes the meshwork surface and facilitates the outflow of aqueous humor.

To perform a *trabeculectomy*, the surgeon dissects a flap of sclera to expose the trabecular meshwork. The surgeon removes a small tissue block and performs a peripheral iridectomy, which produces an opening for aqueous outflow under the conjunctiva and creates a filtering bleb. Postoperatively, subconjunctival injections of fluorouracil may be given to maintain the fistula's patency.

Angle-closure glaucoma is an emergency that requires immediate treatment to reduce high IOP. Initial preoperative drug therapy lowers IOP with acetazolamide, pilocarpine (which constricts the pupil, forces the iris away from the trabeculae, and allows fluid to escape), and I.V. mannitol or oral glycerin (which forces fluid from the eye by making the blood hypertonic). If these medications fail to decrease the pressure, laser iridotomy or surgical peripheral iridectomy must be performed promptly to save the patient's vision.

An *iridectomy* is used to relieve pressure by excising part of the iris to reestablish the outflow of aqueous humor. A few days later, the surgeon performs a prophylactic iridectomy on the other eye. This prevents an episode of acute glaucoma in the normal eye.

If the patient has severe pain, treatment may include narcotic analgesics. After peripheral iridectomy, treatment includes cycloplegic eyedrops to relax the ciliary muscle and to decrease inflammation and thereby prevent adhesions. The end stage of glaucoma may require a tube shunt or valve to keep IOP down.

Nursing diagnoses

- u Anxiety
- u Fear
- u Knowledge deficit
- u Pain
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will express feelings of comfort.
- u The patient and family members will express their feelings and concerns.
- u The patient won't experience harm or injury.
- u The patient will regain visual function.

Nursing interventions

- u For the patient with angle-closure glaucoma, give medications as ordered and prepare him physically and psychologically for laser iridotomy or surgery.
- u Remember to administer cycloplegic eyedrops in the affected eye only. In the unaffected eye, these drops may precipitate an attack of angle-closure glaucoma and threaten the patient's residual vision.
- u After trabeculectomy, give medications as ordered to dilate the pupil. Also apply topical corticosteroids, as ordered, to rest the pupil.
- u After surgery, protect the affected eye by applying an eye patch and shield, positioning the patient on his back or unaffected side, and following general safety measures.
- u Administer pain medication as ordered.
- u Encourage ambulation immediately after surgery.
- u Encourage the patient to express concerns related to having a chronic condition.

Patient teaching

- u Stress the importance of meticulous compliance with prescribed drug therapy to maintain low IOP and prevent optic disk changes that cause vision loss.
- u Explain all procedures and treatments, especially surgery, to help reduce the patient's anxiety.
- u Inform the patient that lost vision can't be restored but that treatment can usually prevent further loss.
- u Instruct family members how to modify the patient's environment for safety. For example, suggest keeping pathways clear and reorienting the patient to room layouts, if necessary.
- u Teach the patient signs and symptoms that require immediate medical attention, such as sudden vision change or eye pain.
- u Discuss the importance of glaucoma screening for early detection and prevention. Point out that all people over age 35 should have an annual tonometric examination.

STRABISMUS

Strabismus results from eye misalignment, which produces nonparallel, uncoordinated eye movement that impairs vision. It's also known as heterotropia or slang

terms, such as squint, cross-eye, or walleye.

The prognosis for correction varies with the timing of treatment and the onset of the disease. Depending on the cause, eye muscle imbalances may be corrected by eyeglasses, patching, or surgery. Residual defects in vision and extraocular muscle alignment may persist even after treatment.

Strabismus affects about 2% of the population. The incidence is higher in patients with central nervous system (CNS) disorders, cerebral palsy, and mental retardation.

The disorder takes many forms and is described in various ways. In children, strabismus may be termed as follows:

- u concomitant—the degree of deviation doesn't vary with the direction of gaze
- u nonconcomitant—the degree of deviation varies with the direction of gaze
- u congenital—apparent at birth or during the first 6 months
- u acquired—present during the child's first 30 months.

In children and adults, strabismus that occurs periodically may be considered latent (phoria) or apparent—for example, when the child is tired or sick. Constant strabismus is considered manifest (tropia). Additional descriptive terms signify strabismic direction, for example:

- u esotropia or esophoria—eyes deviate inward
- u exotropia or exophoria—eyes deviate outward
- u hypertropia or hyperphoria—eyes deviate upward
- u hypotropia or hypophoria—eyes deviate downward.

Other classifications describe paralytic and nonparalytic deviations. Both types may be congenital or acquired. The nonparalytic type is typically intermittent (as in latent strabismus, the gaze doesn't deviate all the time), variable (the amount of deviation varies throughout the day), or alternating (the eyes alternate fixation with the nonfixing eye deviating).

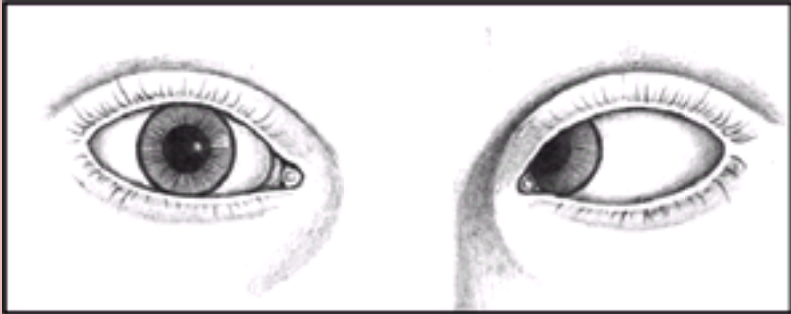

Causes and pathophysiology

In adults, strabismus may result from trauma. In children, controversy continues over whether amblyopia (lazy eye) causes or results from strabismus. Possibly caused by hyperopia (farsightedness) or from anisometropia (unequal refractive power), strabismic amblyopia is characterized by a loss of central vision in one eye. This typically results in esotropia (from fixation by the dominant eye and suppression of images by the deviating eye).

Esotropia (either congenital or acquired) may result from muscle imbalance. In accommodative esotropia, the child's attempt to compensate for farsightedness affects the convergent reflex, and the eyes cross. This subsequent misalignment of the eyes leads to vision suppression in one eye, which in turn causes amblyopia (if misalignment develops early in life before bifoveal fixation is established).

Recognizing strabismus

The patient with strabismus has medial deviation of the left eye.

Complications

Complications of strabismus are limited to diplopia, amblyopia, and other vision disturbances.

Assessment findings

Parents of a child with strabismus typically describe the child as clumsy, frequently stumbling, and bumping into furniture. This description suggests diplopia and lack of depth perception—usually the first indication of strabismus in a child.

Simple observation may disclose apparent eye misalignment. (See [Recognizing strabismus.](#)) Ophthalmoscopic observation of the corneal light reflex in the pupillary center can detect strabismus that is less obvious. Other findings may include ptosis, abnormal head position (tilted to one side), nystagmus, and eye deviation.

ASSESSMENT TIP Deviation of an eye is the second most common symptom in children with retinoblastoma. That is why an acquired strabismus should always be checked.

During inspection you may also notice an overhanging epicanthus. This hallmark of Down syndrome may give a child the appearance of having strabismus (pseudostrabismus). In such a patient, pinch the skin over the bridge of the nose into a fold; if the epicanthal fold disappears, the child may have pseudostrabismus.

In older patients, chief complaints include double vision and unhappiness with appearance.

Diagnostic tests

If the onset of strabismus is sudden or if the CNS is involved, neurologic examination may be used to determine the origin (muscular or neurologic) of the condition.

Other diagnostic procedures are used to determine the best treatment. A visual acuity test is used to evaluate macular vision by determining the patient's vision from a 20' (6-m) distance. Hirschberg's method is used to measure the degree of deviation; as the patient gazes at a light about 13" (33 cm) away, the examiner notes how the cornea reflects light.

Retinoscopy determines refractive error (usually with the pupils dilated), the Maddox rod test is used to assess specific muscle involvement, a convergence test shows distance at which convergence is sustained, and a duction test reveals eye movement limitations.

The cover-uncover test demonstrates eye deviation and the rate of recovery to original alignment. An alternate cover test shows intermittent or latent deviation.

Treatment

Therapy depends on the type of strabismus. For amblyopia, it includes patching the normal eye and prescribing corrective glasses to keep the eye straight and to

counteract farsightedness (as in accommodative esotropia).

Surgery may correct strabismus related to basic esotropia or residual accommodative esotropia after correction with glasses. This may be done to correct misalignment and improve the patient's appearance.

The timing of surgery varies. For example, at age 6 months, an infant with equal visual acuity and obvious esotropia will have the deviation corrected surgically. But a child with unequal visual acuity and an acquired deviation will have the affected eye patched until visual acuity is equal. Then he may undergo surgery.

Surgical correction includes recession (moving the muscle posteriorly from its original insertion) or resection (shortening the muscle). In some patients, combination surgery, such as the resection of one muscle and the recession of its antagonist, is required.

Other procedures involve transplanting a muscle to improve rotation of a paralyzed muscle or using adjustable sutures. Complications may include overcorrection, undercorrection, slipped muscle, and globe perforation.

Postoperative therapy may include patching the affected eye and applying combination antibiotic and corticosteroid eyedrops. Corrective glasses may still be necessary, and surgery may have to be repeated.

The use of botulin neurotoxin A (Botox-A) may be used in conjunction with surgery. The toxin is injected into the extraocular muscle and interferes with the release of acetylcholine at the neuromuscular junction. The antagonist muscle is strengthened over a period of months while the injected muscle is weakened.

Nursing diagnoses

- u Anxiety
- u Body image disturbance
- u Ineffective family coping: Disabling
- u Knowledge deficit
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient and family members will express their feelings and concerns.
- u The patient and family members will express an understanding of the condition and treatment.
- u The patient won't experience harm or injury.
- u The patient will regain visual function.

Nursing interventions

- u Encourage the patient and family members to discuss their feelings about the patient's appearance. Offer emotional support and referrals to appropriate specialists if desired.
- u After surgery, gently blot the patient's tears, which are serosanguineous. Reassure the patient and his parents that this kind of tearing is normal after surgery.
- u Administer antiemetics if necessary.
- u Apply antibiotic ointment as ordered.

Patient teaching

- u Explain all medications and procedures, especially those related to eye surgery.
- u Postoperatively, discourage the patient from rubbing his eyes and prepare him for discharge. (See [Dealing with strabismus.](#))

HOME CARE

Dealing with strabismus

When a patient is being treated for strabismus, follow these guidelines for home care:

- u Help the parents look for and eliminate environmental hazards.
- u Suggest that parents keep pathways clear of objects and assist the patient whenever necessary.
- u Teach the parents or patient how to instill eye medications properly.
- u Teach the parents to recognize adverse drug reactions, emphasizing those that require immediate care.
- u Instruct the parents or patient to blot tears from the cheek — not to wipe them from the eye.
- u Stress the importance of complying with follow-up care.

INTRODUCTION

Although ear, nose, and throat disorders are seldom fatal, they can cause serious social, cosmetic, and communication problems. When left untreated, ear disorders can impair equilibrium and cause hearing loss that drastically impairs communication. Nasal disorders can change facial features and interfere with breathing and taste. Throat disorders can threaten airway patency and interfere with speech.

The ear

The ear is the sensory organ that allows hearing and maintains equilibrium. It consists of three main parts: the external ear, the middle ear, and the inner ear. The skin-covered cartilaginous auricle (pinna), the tympanic membrane, and the external auditory canal compose the external ear. (See [Structures of the external ear.](#))

Separating the external ear and the middle ear at the proximal portion of the auditory canal is the tympanic membrane (eardrum), a pearly gray structure made of layered skin, fibrous tissue, and mucous membrane. The eustachian tube (which connects the middle ear to the nasopharynx) equalizes pressure between the inner and outer surfaces of the tympanic membrane.

On the inner side of the tympanic membrane lies the middle ear, a small, air-filled cavity in the temporal bone. Within the middle ear are three small bones—the malleus, the incus, and the stapes (which sits in an opening called the oval window). These bones are linked together and transmit sound. The middle ear leads to the inner ear, a bony and membranous labyrinth holding endolymph fluid and consisting of the vestibule, the cochlea (containing the organ of Corti), and the semicircular canals.

Hearing and equilibrium

The auricle picks up sound waves and channels them into the auditory canal. There, they strike the tympanic membrane, which vibrates and causes the malleus to vibrate also. These vibrations travel from the malleus to the incus to the stapes, through the oval window and the fluid in the cochlea, to the round window, which opens to the inner ear. The membrane covering the round window shakes the delicate hair cells in the organ of Corti, which stimulates the sensory endings of the cochlear branch of the acoustic nerve (cranial nerve VIII). The nerve sends the impulses to the auditory area of the brain's temporal lobe, which then interprets the sound.

Inner ear structures also maintain equilibrium and balance by means of the fluid in the semicircular canals. This fluid is set in motion by body movement and stimulates nerve cells that line the canals. These cells, in turn, transmit impulses to the brain by way of the vestibular branch of the acoustic nerve.

The ear can respond to sounds with frequencies of 20 to 20,000 hertz (Hz). The range of normal speech is 250 to 4,000 Hz, with 70% of it falling between 500 and 2,000 Hz. The decibel (dB), a measurement of sound intensity, is the lowest volume at which any given sound can be heard. A faint whisper registers 10 to 15 dB; average conversation, 50 to 60 dB; a shout, 85 to 90 dB. Hearing damage can follow exposure to sounds louder than 90 dB.

Assessing the ear

After obtaining a thorough history of ear disease, ask whether the patient has experienced episodes of vertigo, tinnitus, infection, otalgia, or ear pain. To test for vertigo, have the patient stand on one foot with his eyes closed or have him walk a straight line with his eyes closed. Ask if he always falls to the same side and if the room seems to be spinning.

Examine ear color and size. The ears should be similarly shaped, colored the same as the face, and sized in proportion to the head. Inspect the auricle and surrounding tissue for deformities, nodules, lumps, skin lesions, and drainage. Check the ear canal for discharge, foreign bodies, and excessive cerumen (some ears normally drain large amounts of cerumen). Also check behind the ear for inflammation, masses, and lesions. If you see inflammation, check for tenderness by moving the auricle and pressing on the tragus and the mastoid process.

Palpate the external ear and the mastoid process (the bony structure beneath and behind the ear) to discover any areas of tenderness or swelling, nodules, lesions, moles, or cysts, and then gently pull the helix of the ear backward to determine if the patient feels tenderness or pain.

Perform an otoscopic examination to help assess the auditory canal and the tympanic membrane.

Inspect and palpate the temporomandibular joints. Evaluate them for movability, approximation (drawing of the bones together), and discomfort. This process should be smooth and painless for a normal patient.

Structures of the external ear

Audiometric testing

To evaluate hearing and determine the type and extent of hearing loss, perform an audiometric test. The simplest but least reliable method for judging hearing acuity consists of covering one of the patient's ears, standing 18" to 24" (46 to 61 cm) from the uncovered ear, and whispering a short phrase or series of numbers, also known as the whispered voice test. (Block the patient's vision to prevent lip reading.) Then ask the patient to repeat the phrase or series of numbers. To test hearing at both high and low frequencies, repeat the test in a normal speaking voice. (As an alternative, hold a ticking watch to the patient's ear.) Ask if the patient hears better in one ear or the other.

CULTURAL TIP Ensure that the patient speaks the same language as you to have an accurate test. An interpreter may be necessary to ensure the patient understands the instructions.

If you identify a hearing loss, do further testing to determine if the loss is conductive or sensorineural. A conductive loss can result from faulty bone conduction (inability of the acoustic nerve to respond to sound waves traveling through the skull) or faulty air conduction (impaired transmission of sound through ear structures to the acoustic nerve and, ultimately, the brain). A sensorineural loss results from nerve damage. A tuning fork provides a general estimate of hearing loss.

The following tests are used to assess bone and air conduction:

- *Weber's test* (used to test unilateral hearing loss). To perform this test, place the base of a lightly vibrating tuning fork on the midline of the patient's forehead or firmly in the middle of the patient's head. Normally, the patient should hear sounds equally in both ears. In conductive hearing loss, sound lateralizes (localizes) to the ear with the poorest hearing. In sensorineural loss, sound lateralizes to the better functioning ear.
- *Rinne test* (used to compare bone conduction with air conduction). To assess bone conduction, place the base of a vibrating tuning fork on the mastoid process, noting how many seconds pass before the patient can no longer hear it. Then, to assess air conduction, place the still-vibrating tuning fork near the ear canal, with the tines parallel to the patient's auricle. Hold the tuning fork in this position until the patient no longer hears the tone.

In patients with normal hearing and in those with sensorineural loss, the air-conducted tones are heard longer, normally twice as long or longer, than the bone-conducted tones (positive Rinne test). In conductive loss, the patient hears a bone-conducted tone for as long as or longer than he hears an air-conducted tone (negative Rinne test).

After the hearing loss is identified as conductive, sensorineural, or mixed, further audiometric testing is used to determine the extent of the loss. These audiometric tests include pure tone audiometry, speech audiometry, impedance audiometry, and tympanometry.

▫ *Pure tone audiometry* uses an audiometer to produce a series of pure tones of calibrated loudness (dB) at different frequencies (25 to 8,000 Hz). These test tones are conveyed to the patient's ears through headphones or a bone conduction (sound) vibrator. Speech threshold represents the loudness at which a person with normal hearing can perceive the tone. Both air and bone conduction are measured for each ear, and the results are plotted on a graph. If hearing is normal, the line is plotted at 10 dB. In adults, normal hearing may range from 0 to 25 dB.

▫ *Speech audiometry* uses the same technique as pure tone audiometry but with speech, instead of pure tones, transmitted through the headphones. (A person with normal hearing can hear and repeat 88% to 100% of transmitted words.)

▫ *Impedance audiometry* is used to detect middle ear pathology, precisely determining the degree of tympanic membrane and middle ear mobility. One end of the impedance audiometer, a probe with three small tubes, is inserted into the external canal; the other end is attached to an oscillator. One tube delivers a low tone of variable intensity; the second contains a microphone; and the third, an air pump. A mobile tympanic membrane reflects the minimal sound waves and produces a low-voltage curve on the graph. A tympanic membrane with decreased mobility reflects maximal sound waves and produces a high-voltage curve.

▫ *Tympanometry*, for which an impedance audiometer is used, measures tympanic membrane compliance to air pressure variations in the external canal and is used to determine the degree of negative pressure in the middle ear.

The nose, sinuses, mouth, and throat

The sensory organ for smell is the *nose*, which consists of bone and cartilage. The nose is separated into nostrils (nares) by the nasal septum. Lining the vestibule at the nostril entrance are cilia (tiny hairs). As air filters past the cilia and over mucosa-lined passages to bony structures called turbinates, it is warmed, filtered, and humidified. The nose ends at the posterior air passages known as the choanae, which lead to the oropharynx.

The *sinuses* lie within the facial bones. Hollow, air-filled cavities, they include the frontal, sphenoid, ethmoid, and maxillary sinuses. The same mucous membrane lines the sinuses and the nasal cavity. Consequently, the same viruses and bacteria that cause upper respiratory tract infections also infect the sinuses. Besides aiding voice resonance, the sinuses may help warm, filter, and humidify inhaled air, although this role hasn't been firmly established.

The sensory organ for taste, the *mouth* begins externally at the lips and continues with the tongue, gingivae, teeth, and salivary glands. The frenulum (a restraining band of tissue) attaches the tongue to the floor of the mouth. The gingivae cover the necks and roots of the teeth. Near the beginning of the throat, the anterior and posterior pillars form a cavity that houses the tonsils. Located nearby, three pairs of salivary glands—parotid (near the ear), sublingual (under the tongue), and submandibular (adjacent to the parotid glands)—keep the mouth moist. Bordering the mouth posteriorly are the soft palate and the uvula. Other boundaries include the mandibular bone forming the floor of the mouth and the hard palate that forms the roof of the mouth.

The *throat*—located in the anterior part of the neck—includes the pharynx, epiglottis, and larynx. Food travels through the pharynx to the esophagus. Air travels through it to the larynx. The epiglottis diverts material away from the glottis during swallowing. By vibrating expired air through the vocal cords, the larynx produces sounds. Changes in vocal cord length and air pressure affect the pitch and intensity of the voice. The larynx also stimulates the vital cough reflex when a foreign body touches its sensitive mucosa.

Assessing the nose

Inspect the external nose for symmetry and contour, noting any areas of deformity, swelling, and discoloration. Check for redness, edema, lumps, tumors, and poor alignment. Marked septal cartilage depression may indicate saddle deformity due to septal destruction from trauma or congenital syphilis. Extreme lateral deviation could mean there is septal destruction due to injury. Red nostrils may indicate frequent nose blowing caused by allergies or infectious rhinitis. Dilated, engorged blood vessels may suggest alcoholism or constant exposure to the elements. A bulbous, discolored nose may be a sign of rosacea.

With a nasal speculum and adequate lighting, check the nasal mucosa for pallor and edema, redness and inflammation, dried mucus plugs, furuncles, and polyps. Also look for abnormal appearance of capillaries and a deviated or perforated septum. Check for nasal discharge (assess its color, consistency, and odor) and blood. A profuse, thin, watery discharge may stem from an allergy or a cold; a profuse, thin, purulent discharge can indicate a cold or a chronic sinus infection.

Palpate the nose, checking for any painful or tender areas, swelling, and deformities. Evaluate nostril patency by gently occluding one nostril with your finger and having the patient exhale through the other.

Assessing the sinuses

To assess the paranasal sinuses, inspect, palpate, and percuss the frontal and maxillary sinuses (location of the other sinuses precludes assessment). First, inspect the external skin surfaces above and to the side of the nose for inflammation and edema. Then palpate and percuss the sinuses.

Pain after pressure is applied above the upper orbital rims indicates frontal sinus irritation; pain after pressure is applied to the cheeks, maxillary sinus irritation.

Assessing the mouth and throat

Using a bright light, gloves, and a tongue blade, inspect the patient's mouth and throat. Note any unusual breath odors. Look for inflammation, white patches, and any irregularities on the tongue and throat.

Assess vital signs and respiratory status. Make sure the patient's airway isn't compromised. Watch for and immediately report signs of respiratory distress (dyspnea, tachycardia, tachypnea, inspiratory stridor, restlessness) and changes in voice or skin color, such as circumoral or nail bed cyanosis.

Assess the symmetry of the tongue and function of the soft palate. To assess the underside of the tongue, have the patient touch the roof of his mouth with the tip of his tongue. Inspect the hard and soft palates. Note any deformities, lesions, areas of tenderness or inflammation, and other abnormalities.

Observe the tonsils for unilateral or bilateral enlargement. Inspect the maxillary mucobuccal fold and the labial frenulum for irritation and inflammation. Palpate the upper and lower lips and tongue to evaluate muscle tone and surface structure.

External ear disorders

Disorders of the external ear are fairly common and are typically caused by routine activities, such as ear piercing and the use of cotton-tipped applicators and hair-care products. Although seldom life-threatening, these disorders can result in hearing loss and other complications if left untreated.

BENIGN TUMORS OF THE EAR CANAL

Benign tumors can develop anywhere in the ear canal. Common benign tumors include keloids, osteomas, and sebaceous cysts. Blacks and young women are most susceptible to keloids, which tend to recur. Osteomas are three times more common in males than in females.

These tumors seldom become malignant; with proper treatment, the prognosis is excellent.

Causes

Keloids result from an overgrowth of collagenous scar tissue at the site of a wound or traumatic injury such as ear piercing. Osteomas are of idiopathic origin. Sebaceous cysts result from obstruction of a sebaceous gland, and they can be congenital.

Complications

Benign tumors can cause hearing loss.

Assessment findings

The patient usually doesn't report any symptoms unless the tumor becomes infected, in which case he may complain of pain and fever or inflammation. A patient history of pain is commonly a symptom of a malignant tumor.

ASSESSMENT TIP Malignant tumors may be found in the external ear. The most common cutaneous carcinomas are basal cell carcinomas on the pinna and squamous cell carcinomas on the ear canal. If left untreated, the carcinoma can invade the underlying tissue.

On otoscopic examination, a keloid appears as elevated tissue that is round and firm, with irregular margins.

Osteomas usually occur bilaterally and in multiples (exostoses) and appear as bony outgrowths from the wall of the external auditory meatus.

A sebaceous cyst usually is palpated behind the ear near the lobule or meatus within the skin and appears as a small cyst with a black dot in the center. The cheeselike contents of the cyst have a rancid odor. (See [Causes and characteristics of benign ear tumors.](#))

Diagnostic tests

When otoscopic examination confirms a tumor, biopsy is used to rule out cancer.

ADVANCED PRACTICE

Causes and characteristics of benign ear tumors

TUMOR	CAUSES AND INCIDENCE	CHARACTERISTICS
<i>Keloid</i>	<ul style="list-style-type: none">▫ Surgery or trauma such as ear-piercing▫ Most common in blacks	<ul style="list-style-type: none">▫ Hypertrophy and fibrosis of scar tissue▫ Commonly recurs
<i>Osteoma</i>	<ul style="list-style-type: none">▫ Idiopathic growth▫ Predisposing factor: swimming in cold water▫ Three times more common in males than in females▫ Seldom occurs before adolescence	<ul style="list-style-type: none">▫ Bony outgrowth from wall of external auditory meatus▫ Usually bilateral and multiple (exostoses)▫ May be circumscribed or diffuse, nondisplaceable, nontender
<i>Sebaceous cyst</i>	<ul style="list-style-type: none">▫ Obstruction of a sebaceous gland	<ul style="list-style-type: none">▫ Painless, circumscribed, round mass of variable size filled with oily, fatty, glandular secretions▫ May occur on external ear and outer third of external auditory canal

Treatment

A benign tumor usually requires surgical excision if it obstructs the ear canal, is cosmetically undesirable, or becomes malignant.

Treatment for a patient with a keloid may include surgery, followed by repeated injections of long-acting steroids into the suture line. Excision must be complete, but even this may not prevent recurrence.

Surgical excision of an osteoma consists of elevating the skin from the surface of the bony growth and shaving the osteoma with a mechanical burr or drill.

Before surgery, a patient with a sebaceous cyst requires preliminary treatment with antibiotics to reduce inflammation. To prevent recurrence, excision must be complete, including the sac or capsule of the cyst.

Nursing diagnoses

- Anxiety
- Impaired skin integrity
- Knowledge deficit
- Pain
- Risk for infection
- Sensory or perceptual alterations

Key outcomes

- The patient and family members will express an understanding of the disorder or treatment.
- The patient will remain free from signs and symptoms of infection.
- The patient will express feelings of comfort.
- The patient will regain hearing or develop compensation mechanisms to communicate.

Nursing interventions

- Answer the patient's questions, encourage him to express his concerns, and offer reassurance when appropriate.

Patient teaching

- After surgery, instruct the patient in good aural hygiene. Until the ear is completely healed, advise the patient not to insert anything into it or to allow water into it. Suggest that he cover the ears with a cap when showering.
- Tell the patient to report immediately any signs of infection, such as pain, fever, localized redness, and swelling.
- Counsel the patient to take antibiotics at the times prescribed and to finish the prescription. Alert him to watch for and report any signs of an adverse reaction.

OTITIS EXTERNA

Otitis externa is an acute or chronic inflammation of the skin of the external ear canal and auricle. It occurs most commonly during the summer but can occur at any time of the year.

WARNING

Neomycin alert

Neomycin, which is commonly used to treat otitis externa, may itself be the cause of contact dermatitis. Worsening of otitis externa 1 to 3 days after starting neomycin drops, along with itching and burning in a reddened area below the ear, may indicate contact dermatitis.

With treatment, acute otitis externa usually subsides within 7 days; however, it may become chronic and tends to recur. Severe, chronic otitis externa may reflect underlying diabetes mellitus, hypothyroidism, or nephritis.

Other names for this disorder are external otitis and swimmer's ear.

Causes

Otitis externa usually results when a traumatic injury or an excessively moist ear canal predisposes the area to infection. Common infecting organisms include bacteria, such as *Pseudomonas*, *Proteus vulgaris*, streptococci, *Staphylococcus aureus*, *Escherichia coli*, *Proteus mirabilis*, and *Klebsiella*; and, less commonly, fungi, such as *Aspergillus niger* and *Candida albicans* (fungal otitis externa is most common in the tropics). Occasionally, chronic otitis externa results from dermatologic conditions, such as seborrhea or psoriasis.

Predisposing factors include:

- swimming in contaminated water (Cerumen creates a culture medium for the waterborne organism.)
- cleaning the ear canal with a cotton-tipped applicator, bobby pin, finger, or other object, which irritates the ear canal and may introduce the infecting microorganism
- exposure to dust, hair-care products, or other irritants, which causes the patient to scratch the ear, excoriating the auricle and canal
- regular use of earphones, earplugs, or earmuffs, which trap moisture in the ear canal, creating a culture medium for infection

- u chronic drainage from a perforated tympanic membrane.

Complications

Without effective treatment, otitis externa can lead to a complete closure of the ear canal, causing significant hearing loss. The infection may progress to the middle ear, resulting in otitis media. In severe otitis externa, cellulitis may develop, requiring oral or parenteral antibiotic therapy. In addition, abscesses, discolorations, disfigurement of the pinna, lymphadenopathy, osteitis, septicemia, and stenosis can occur.

Malignant otitis externa, most common in patients with type I diabetes mellitus, may develop as a result of a fulminant *Pseudomonas* infection.

Assessment findings

A review of the patient history usually shows repeated exposure to ear trauma, water, use of earphones, or allergic response to hair spray, dye, or other hair-care products. The patient also may relate a history of mild to severe ear itching or pain (or both) that is aggravated by jaw motion, clenching the teeth, opening the mouth, or chewing.

Inspection may reveal a swollen, inflamed ear canal and an ear discharge that may be foul-smelling. In chronic otitis externa, inspection shows a thick, red epithelium in the ear canal. The patient may complain of increased pain or itching on palpation or manipulation of the pinna or tragus.

Otoscopy reveals a swollen external ear canal (sometimes to the point of complete closure), periauricular lymphadenopathy (tender nodes in front of the tragus, behind the ear, or in the upper neck) and, occasionally, regional cellulitis.

Fungal otitis externa may be asymptomatic, although *A. niger* may appear on otoscopy as a black or gray, inkblotlike growth in the ear canal.

Diagnostic tests

Audiometric testing may reveal a partial hearing loss. Microscopic examination or culture and sensitivity tests can be used to identify the causative organism and determine antibiotic treatment. In fungal otitis externa, removal of the growth reveals thick, red epithelium.

Treatment

Treatment—emphasizing site care and drug therapy—includes:

- u cleaning debris from the ear canal with suction and small cotton-tipped applicators under direct visualization through an ear speculum
- u instilling antibiotic or anti-inflammatory drops—a combination of polymyxin B, neomycin, and hydrocortisone (Cortisporin Otic solution) to manage gram-negative and gram-positive organisms and to decrease inflammation
- u inserting an ear wick or a piece of medicine-soaked cotton into the ear (when the canal is moderately or severely swollen) for 24 to 48 hours. (See [Neomycin alert.](#))
- u administering analgesics as appropriate
- u administering systemic antibiotics to combat systemic signs such as fever. Corticosteroids may be used with antibiotic drops.

Surgery may be needed to excise and drain an abscess.

For the patient with a fungal infection, treatment includes:

- u cleaning the ear carefully
- u applying a keratolytic or 2% salicylic acid in cream containing nystatin for candidal organisms
- u instilling slightly acidic eardrops to create an unfavorable environment in the ear canal for most fungi as well as *Pseudomonas*.

In *chronic otitis externa*, treatment involves:

- u cleaning the ear and removing debris
- u instilling antibiotic eardrops or applying antibiotic ointment or cream (neomycin, bacitracin, or polymyxin B, possibly combined with hydrocortisone). An ointment containing phenol, salicylic acid, precipitated sulfur, and petroleum jelly, which produces exfoliative and antipruritic effects, also may be used.

For *mild chronic otitis externa*, treatment includes:

- u instilling antibiotic eardrops once or twice weekly
- u wearing specially fitted earplugs while showering, shampooing, or swimming.

Nursing diagnoses

- u Fear
- u Impaired skin integrity
- u Impaired verbal communication
- u Knowledge deficit
- u Pain
- u Risk for infection
- u Sensory or perceptual alterations

Key outcomes

- u The patient will remain free from signs and symptoms of infection.
- u The patient will express feelings of comfort.
- u The patient will express an understanding of the disorder and treatment.
- u The patient will communicate needs and feelings.
- u The patient will regain hearing function or develop alternative ways to communicate.

Nursing interventions

- u Answer the patient's questions, and encourage him to discuss concerns about hearing loss. Offer reassurance when appropriate.
- u If the patient has difficulty understanding procedures because of hearing loss, give clear, concise explanations of treatments and procedures. Face him when speaking; enunciate words clearly, slowly, and in a normal tone; and allow adequate time for him to grasp what you've said. Provide a pencil and paper to aid communication and alert the staff to his communication problem.
- u If the patient has chronic otitis externa, clean the ear thoroughly. Use wet soaks intermittently on oozing or infected skin.
- u If the patient has a chronic fungal infection, clean the ear canal well and then apply an exfoliative ointment.

If the patient has acute otitis externa:

- u Monitor vital signs, especially temperature. Watch for and record the type and amount of aural drainage.
- u Remove debris and gently clean the ear canal with mild Burow's solution (aluminum acetate). Place a wisp of cotton soaked with solution into the ear and apply a saturated compress directly to the auricle. Afterward, dry the ear gently and thoroughly. (In severe otitis externa, such cleaning may be delayed until after initial treatment with antibiotic eardrops.)
- u To instill eardrops in an adult, pull the pinna upward and backward to straighten the canal. To ensure that the drops reach the epithelium, insert a wisp of cotton moistened with eardrops.

Patient teaching

- u Instruct the patient in proper hand washing and daily ear cleaning.
- u Teach the patient and family members how to properly instill ear drops, ointment, and ear wash.
- u Reassure the patient that hearing loss from an external ear infection is temporary.
- u Caution the patient to take antibiotics on time, to finish the prescription, and to report any adverse reactions. (See [Preventing otitis externa.](#))

PREVENTION

Preventing otitis externa

- u To prevent recurrence, tell the patient to avoid potential irritants, such as hair-care products and earrings.
- u Advise the patient to use lamb's wool earplugs coated with petroleum jelly to keep water out of the ears when showering or shampooing.
- u Inform parents of a young child that modeling clay makes a tight seal and can be used to prevent water from getting into the external canal.
- u Tell the patient to wear earplugs or to keep his head above water when swimming and to instill two or three drops of 3% boric acid solution in 70% alcohol into the ear before and after swimming to toughen the skin of the external ear canal.
- u Warn against cleaning the ears with cotton-tipped applicators or other objects.

Middle ear disorders

Disorders of the middle ear most commonly result from viral or bacterial infections; they also may be genetic in origin. Some of these disorders can easily become chronic, causing irreparable hearing loss. However, proper treatment with antibiotics, surgery, or both usually produces a good prognosis.

INFECTIOUS MYRINGITIS

Acute infectious myringitis is characterized by inflammation, hemorrhage, and effusion of fluid into the tissue at the end of the external ear canal and the tympanic membrane. This is a self-limiting disorder that resolves spontaneously within 3 days to 2 weeks.

Acute infectious myringitis commonly follows acute otitis media or upper respiratory tract infection and frequently occurs epidemically in children. Chronic granular myringitis is a rare inflammation of the squamous layer of the tympanic membrane. Bullous myringitis causes retraction of the tympanic membrane due to negative pressure in the ear.

Causes

Acute infectious myringitis usually follows viral infection but may result from infection with bacteria (pneumococci, *Haemophilus influenzae*, beta-hemolytic streptococci, and staphylococci) or any other organism that can cause acute otitis media. Myringitis is a rare sequela of atypical pneumonia caused by *Mycoplasma pneumoniae*.

The cause of chronic granular myringitis is unknown.

Complications

Chronic granular myringitis may lead to stenosis of the ear canal and gradual hearing loss.

Assessment findings

The patient with acute infectious myringitis may complain of severe ear pain, commonly accompanied by tenderness over the mastoid process. In chronic granular myringitis, the patient's history may reveal pruritus, purulent discharge, and gradual hearing loss.

Otoscopic examination reveals small, reddened, inflamed blebs in the ear canal, on the tympanic membrane and, with bacterial invasion, in the middle ear. Spontaneous rupture of these blebs may cause a bloody discharge. In chronic granular myringitis, examination may reveal granulation extending from the tympanic membrane to the external ear.

Fever and hearing loss are rare unless fluid accumulates in the middle ear or a large bleb completely obstructs the external auditory meatus.

Diagnostic tests

Culture and sensitivity testing of exudate identifies secondary infection.

Treatment

Hospitalization usually isn't required for patients with acute infectious myringitis. Treatment consists of:

- u analgesics, such as aspirin or acetaminophen, to relieve pain
- u application of heat to the external ear
- u codeine for severe pain
- u systemic or topical antibiotics to prevent or treat secondary infection
- u incision of blebs and evacuation of serum and blood to relieve pressure and help drain exudate. (*Note:* These measures don't speed recovery.)

Treatment of chronic granular myringitis consists of systemic antibiotics or local anti-inflammatory antibiotic combination eardrops and surgical excision and cautery. If stenosis is present, surgical reconstruction is necessary.

Nursing diagnoses

u Anxiety u Impaired skin integrity u Impaired verbal communication u Knowledge deficit u Pain u Risk for infection u Sensory or perceptual alterations u Sleep pattern disturbance

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express an understanding of the disorder and treatment.

- u The patient will regain hearing or develop alternative ways of communicating.

Nursing interventions

- u Answer the patient's questions, encourage him to express his concerns about hearing loss, and offer reassurance when appropriate.
- u If the patient has difficulty understanding procedures because of hearing loss, give clear, concise explanations of treatments and procedures. Face him when speaking; enunciate words clearly, slowly, and in a normal tone; and allow adequate time for him to grasp what is expected. Provide a pencil and paper to aid communication and alert the staff to his communication problem.
- u Assess the patient's level of pain and give analgesics as needed. Also give antibiotic eardrops as ordered. Monitor the response to these medications.
- u To instill eardrops in an adult, pull the pinna upward and backward to straighten the canal. To ensure that the drops reach the epithelium, insert a wisp of cotton moistened with eardrops.

Patient teaching

- u Explain all procedures such as bleb incision.
- u Stress the importance of completing the prescribed antibiotic therapy. Advise the patient to report any adverse reactions.
- u Review purpose, dosage, administration and possible adverse effects of medications ordered.
- u Teach the patient or family members how to instill antibiotic eardrops.
- u Teach proper instillation of drops by pulling the aeriole up and back to straighten the auditory canal.
- u Explain the signs and symptoms of infectious myringitis and the necessity for prompt treatment of otitis media.

Understanding mastoiditis

Mastoiditis—bacterial infection and inflammation of the air cells of the mastoid antrum—is a complication of chronic otitis media or, less frequently, acute otitis media.

Mastoiditis may result from ineffective antibiotic selection or poor patient compliance. Chronic infection can lead to cholesteatoma, a cystlike benign growth. Purulence in the middle ear causes necrosis of adjacent tissue and extension of the infection into the mastoid cells. Chronic systemic diseases or immunosuppression also may lead to mastoiditis. Spreading infection can cause facial paralysis, labyrinthitis, meningitis, and other complications.

The patient may have a dull earache and tenderness, purulent discharge, a low-grade fever, swelling and obstruction of the ear canal, and hearing loss.

X-ray results confirm the diagnosis, and audiometric testing discloses hearing loss. Culture and sensitivity test results identify the causative agent. Biopsy, computed tomography scanning, and magnetic resonance imaging aid the diagnosis. A complete blood count may reveal systemic infection.

Parenteral antibiotic therapy is the primary treatment. If bone damage is minimal, myringotomy is performed to drain fluid. Persistent infection, intracranial complications, and chronic mastoiditis may necessitate simple or radical mastoidectomy, sometimes causing permanent hearing loss.

OTITIS MEDIA

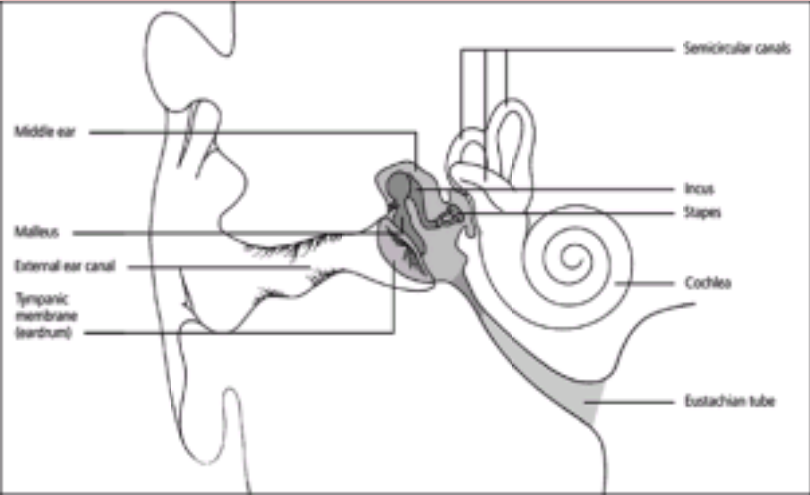

Otitis media, an inflammation of the middle ear associated with fluid accumulation, may be acute or chronic, suppurative or secretory.

Acute otitis media is most common in infants and children because they have a shorter and more horizontal eustachian tube than adults, which predisposes them to middle ear infections. The incidence peaks between ages 6 and 24 months and subsides after age 3. It occurs most frequently during the winter months, paralleling the seasonal increase in nonbacterial respiratory tract infections.

With prompt treatment, the prognosis for acute otitis media is excellent. However, prolonged accumulation of fluid in the middle ear cavity can cause chronic serous otitis media, with possible perforation of the tympanic membrane. Chronic suppurative otitis media can lead to scarring, adhesions, and severe structural or functional ear damage. Chronic secretory otitis media, with its persistent inflammation and pressure, can cause conductive hearing loss. (See [Sites of otitis media.](#))

Sites of otitis media

The shaded areas of the middle ear in the illustration below denote sites of otitis media.

Causes

Acute otitis media results from disruption of eustachian tube patency.

Suppurative otitis media usually results from bacterial infection with pneumococci, *Haemophilus influenzae* (the most common cause in children under age 6), beta-hemolytic streptococci, staphylococci (the most common cause in children age 6 or older), and gram-negative bacteria. In this disorder, respiratory tract infections, allergic reactions, and position changes, such as holding an infant in a supine position during feeding, allow reflux of nasopharyngeal flora through the eustachian tube and colonization in the middle ear.

Chronic suppurative otitis media results from inadequate treatment of acute otitis episodes or from infection by resistant strains of bacteria.

Secretory otitis media stems from a viral infection, an allergy, or barotrauma (pressure injury from an inability to equalize pressures between the environment and the middle ear), such as that experienced during rapid aircraft descent or rapid underwater ascent in scuba diving (barotitis media). In this disorder, obstruction of the eustachian tube promotes transudation of sterile serous fluid from blood vessels in the middle ear membrane.

Chronic secretory otitis media is caused by adenoidal tissue overgrowth that obstructs the eustachian tube, edema resulting from allergic rhinitis, chronic sinus

infection, or inadequate treatment of acute suppurative otitis media.

Complications

Spontaneous rupture of the tympanic membrane can cause persistent perforation that may develop into chronic otitis media. Other complications are mastoiditis, meningitis, cholesteatomas (cystlike masses in the middle ear), septicemia, abscesses, vertigo, lymphadenopathy, leukocytosis, and permanent hearing loss. (See [Understanding mastoiditis](#).) Tympanosclerosis results from repeated ear infections. It's a deposit of collagen and calcium in the middle ear that hardens around the ossicles, causing conduction hearing loss.

Assessment findings

The patient history may reveal an upper respiratory tract infection or history of allergies. The patient may complain of severe, deep, throbbing ear pain (from pressure behind the tympanic membrane) and dizziness, nausea, and vomiting. With acute secretory otitis media, the patient may describe a sensation of fullness in the ear and popping, crackling, or clicking sounds on swallowing or moving the jaw. The patient with an accumulation of fluid may describe hearing an echo when speaking and experiencing a vague feeling of top-heaviness.

If the tympanic membrane has ruptured, the patient may state that the pain suddenly stopped. A history of recent air travel or scuba diving suggests barotitis media.

Inspection may reveal sneezing and coughing due to an upper respiratory tract infection. Vital sign assessment may reveal mild to very high fever. In chronic suppurative otitis media, inspection may reveal a painless, purulent discharge.

In acute suppurative otitis media, otoscopic examination may show obscured or distorted bony landmarks of the tympanic membrane. In acute secretory otitis media, otoscopy reveals tympanic membrane retraction, which causes the bony landmarks to appear more prominent. Otoscopy also reveals clear or amber fluid behind the tympanic membrane, possibly with a meniscus and bubbles. If hemorrhage into the middle ear has occurred, as in barotrauma, otoscopy exposes a blue-black tympanic membrane.

In chronic otitis media, otoscopic examination may show thickening and scarring of the tympanic membrane, decreased or absent tympanic membrane mobility, or cholesteatoma. If a tympanic perforation is present, a pulsating discharge may be visible.

In acute secretory otitis media, audiometric tests may reveal severe conductive hearing loss varying from 15 to 35 dB, depending on the thickness and amount of fluid in the middle ear cavity. In chronic suppurative otitis media, the associated conductive hearing loss varies with the size and type of tympanic membrane perforation and ossicular destruction.

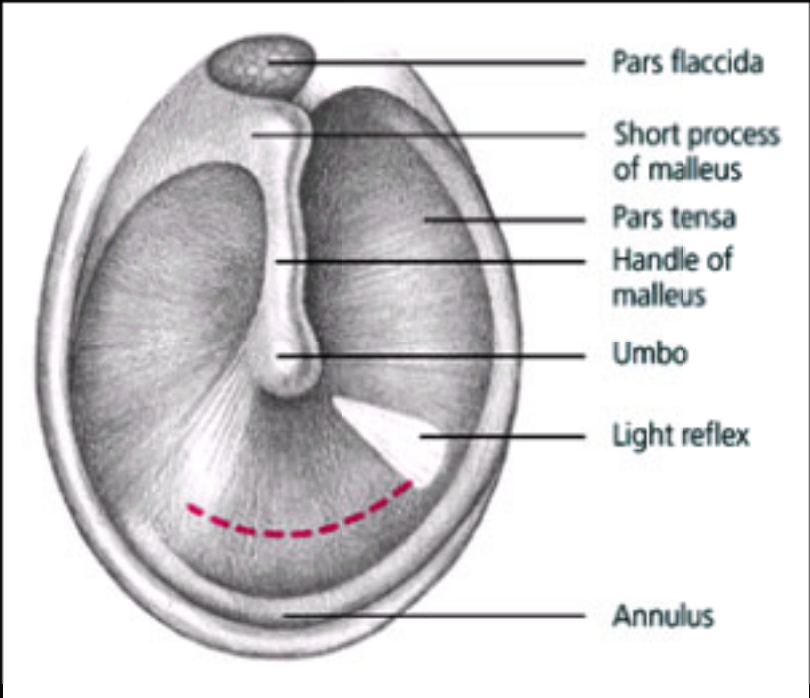

Diagnostic tests

Otoscopic or neuroscopic examination is used to diagnose the disorder, remove debris, and perform minor surgery.

Pneumatoscapy shows decreased tympanic membrane mobility. (This procedure is painful when the tympanic membrane is obviously bulging and erythematous.) Tympanometry is used to measure how well the tympanic membrane functions to detect hearing loss and evaluate the condition of the middle ear.

Myringotomy

Myringotomy (also called tympanocentesis) is the surgical puncture of the tympanic membrane for removal of fluid from the middle ear. The semicircular incision is made along the bottom arc of the membrane (shown below, with other landmarks).

Culture and sensitivity tests of exudate are used to identify the causative organism.

Radiographic studies depict mastoid involvement. Audiometry is used to detect and measure the degree of hearing loss.

Biopsy is used to rule out malignancy and identify tissues and a complete blood count is used to identify infection.

Treatment

In acute suppurative otitis media, antibiotic therapy includes ampicillin or amoxicillin and, also, amoxicillin clavulanate potassium (Augmentin) for infants, children, and adults. Therapy for patients allergic to penicillin derivatives may include sulfonamides, erythromycin, tetracycline, and other broad-spectrum antibiotics. Aspirin or acetaminophen controls pain and fever.

Severe, painful bulging of the tympanic membrane usually requires myringotomy. (See [Myringotomy](#).) Codeine may be given for severe pain in adults, and sedatives may be given to small children.

HOME CARE

Preventing otitis media

For a patient recovering from otitis media at home, follow these guidelines to help prevent a recurrence:

- u Teach the patient how to recognize upper respiratory tract infections and encourage early treatment of them.
- u Instruct parents not to feed an infant in a supine position and not to put him to bed with a bottle. Explain that doing so could cause reflux of nasopharyngeal flora.
- u Teach the patient to promote eustachian tube patency by performing Valsalva's maneuver several times a day, especially during airplane travel.
- u After tympanoplasty, advise the patient not to blow his nose or get his ear wet when bathing.
- u Explain all adverse reactions to the prescribed medication, emphasizing those that require immediate medical attention.

Broad-spectrum antibiotics can help prevent acute suppurative otitis media in high-risk patients such as children with recurring episodes of otitis. In these patients, antibiotics must be used sparingly and with discretion to prevent development of resistant bacteria.

In acute secretory otitis media, performing Valsalva's maneuver several times a day to inflate the eustachian tube may be the only treatment required. If this isn't successful, nasopharyngeal decongestant therapy may be helpful; it should continue for at least 2 weeks and sometimes indefinitely, with periodic evaluation. If decongestant therapy fails, myringotomy and aspiration of middle ear fluid are necessary, followed by insertion of a polyethylene tube into the tympanic membrane to equalize pressure. This pressure-equalizing tube, called a tympanostomy tube, remains in place for 6 to 12 months, although it may fall out on its own. Concomitant treatment of the underlying cause (such as allergen elimination or adenoidectomy) also may be helpful.

Treatment for a patient with chronic otitis media may include antibiotics for exacerbations of acute otitis media, elimination of eustachian tube obstruction, treatment of otitis externa (when present), myringoplasty (tympanic membrane graft), tympanoplasty to reconstruct middle ear structures when thickening and scarring are present, mastoidectomy, or cholest-eatoma excision.

A stapedectomy may be performed for a patient with otosclerosis.

Nursing diagnoses

u Altered nutrition: Less than body requirements u Impaired verbal communication u Knowledge deficit u Pain u Risk for infection u Risk for injury u Sensory or perceptual alterations u Sleep pattern disturbance

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient and family members will verbalize an understanding of the disorder and treatment regimen.
- u The patient won't experience injury or harm.
- u The patient will regain hearing or develop compensatory mechanisms.

Nursing interventions

- u Answer the patient's or parents' questions. Encourage them to discuss concerns about hearing loss and offer reassurance when appropriate.
- u If the patient has difficulty understanding procedures because of hearing loss, provide clear, concise explanations. Face him when speaking; enunciate clearly, slowly, and in a normal tone; and allow time for him to grasp what you've said. Provide a pencil and paper and alert the staff to his communication problem.
- u After myringotomy, maintain the drainage flow. Don't place cotton or plugs deep in the ear canal; you may place sterile cotton loosely in the external ear to absorb drainage. To prevent infection, change the cotton when it gets damp and wash your hands before and after ear care. As prescribed, give codeine and aspirin for pain and antiemetics for nausea and vomiting.
- u After tympanoplasty, reinforce dressings and observe for excessive bleeding from the ear canal. Administer analgesics as needed.
- u Identify and treat allergies.

Patient teaching

- u Advise the patient with acute secretory otitis media or his parents to watch for and immediately report pain and fever, which indicate secondary infection.
- u Teach the patient and family members proper instillation of ointment, drops, and ear wash as ordered.
- u Teach the patient and family members how to administer analgesics and medication as ordered, and tell them about possible adverse effects. Stress the importance of taking antibiotics as prescribed to prevent secondary infection.
- u If nasopharyngeal decongestants are ordered, teach correct instillation.
- u Tell the patient that some doctors require fitted earplugs for swimming after myringotomy and tympanostomy tube insertion. Advise the patient to notify the doctor if the tube falls out and if any ear pain, fever, or pus-filled ear discharge occurs.
- u Explain how to prevent recurrence. (See [Preventing otitis media.](#))
- u Encourage a nutritious diet that includes the patient's favorite foods. To ensure adequate fluid intake, include electrolyte drinks. Popsicles, frozen fruit pops, and gelatin desserts are favorable alternatives.
- u Instruct the patient and parents to tell the doctor about any significant earache.
- u Reassure the patient that hearing loss caused by serious otitis media is temporary.

OTOSCLEROSIS

Otosclerosis (or hardening of the ear) is the most common cause of conductive hearing loss. It causes a slow formation of spongy bone in the otic capsule, particularly at the oval window. This otosclerotic bone growth eventually causes the footplate of the stapes to become locked or fixed in position, disrupting the conduction of vibrations from the tympanic membrane to the cochlea.

Otosclerosis occurs in at least 10% of whites, is twice as common in women as in men, and usually occurs between ages 15 and 50. With surgery, the prognosis is good.

Causes

Otosclerosis may result from a genetic factor transmitted as an autosomal dominant trait. Many patients with this disorder report family histories of hearing loss (excluding presbycusis). Pregnancy may trigger the onset of this condition.

Complications

This disorder is unilateral at first and then may advance to bilateral conductive hearing loss.

Types of stapedectomy

Surgery may remove part or all of the stapes, depending on the extent of otosclerotic growth. It may be performed using various techniques. Two techniques used to implant a prosthesis are depicted below.

HOME CARE

Otosclerosis: Recovering after surgery

Review the following points with the patient before discharge:

- Instruct the patient to sneeze and cough with her mouth open for 2 weeks after surgery to prevent dislodgment of the graft or prosthesis.
- Inform the patient that she may hear a variety of noises, such as cracking or popping; reassure her that this is normal.
- Tell the patient that the ear packing or middle ear fluid decreases hearing in the affected ear and it can seem as if she's talking in a barrel.
- Reassure the patient that minor ear discomfort is expected, and urge her to take the prescribed pain medication. Stress that excessive ear pain should be reported to the doctor.
- Occasionally, a small amount of bleeding from the ear occurs; reassure the patient that this is normal. Excessive ear drainage should be reported to the doctor.
- Explain that some patients initially find the improvement in hearing after stapes surgery so great that it causes sensitivity or distress. This usually diminishes as the patient adapts to the improved hearing level.
- Before discharge, instruct the patient to avoid loud noises and sudden pressure changes, such as those that occur while diving or flying, until healing is complete (usually 6 months).
- Advise the patient not to blow her nose for at least 1 week to prevent contaminated air and bacteria from entering the eustachian tube.
- Stress the importance of protecting the ears against cold; avoiding any activities that provoke dizziness, such as straining, bending, or heavy lifting; and, if possible, avoiding contact with anyone who has an upper respiratory tract infection.
- Teach the patient and her family how to change the external ear dressing (eye pad or gauze pad) and care for the incision.
- Emphasize the need to complete the prescribed antibiotic regimen and to return for scheduled follow-up care.

Assessment findings

The patient may report a history of slow, progressive hearing loss in one ear, which may have progressed to both ears, without middle ear infection. She may also describe tinnitus and the ability to hear a conversation better in a noisy environment than in a quiet one (paracusis of Willis).

In 20% to 25% of patients, vertigo is experienced, especially after bending over. The patient may also state that she can hear her own voice. This is because the sound is conducted through the bones in the head. Conversation may be inappropriate due to the inability to hear.

Otoscopic examination usually reveals a tympanic membrane that appears normal. Occasionally, you may see a faint pink blush through the membrane from the

vascularity of the active otosclerotic bone (Schwartz's sign).

Diagnostic tests

A Rinne test demonstrates that the bone-conducted tone is heard longer than the air-conducted tone. (Normally, the reverse is true.) As otosclerosis progresses, bone conduction also deteriorates. Weber's test is used to detect sound lateralizing to the more damaged ear. Audiometric testing reveals hearing loss, ranging from 60 dB in early stages to total loss as the disease advances.

Treatment

In most cases, treatment consists of stapedectomy (removal of the stapes) and insertion of a prosthesis to restore partial or total hearing. This procedure is performed on one ear at a time, beginning with the ear that has sustained greater damage. Postoperative treatment includes hospitalization for 2 to 3 days and antibiotics to prevent infection. (See [Types of stapedectomy.](#))

Other surgical procedures include fenestration and stapes mobilization; all require normal cochlear function. Postoperative treatment includes hospitalization for 2 to 3 days and antibiotics to prevent infection. (See [Otosclerosis: Recovering after surgery.](#))

If surgery isn't possible, hearing aids enable the patient to hear conversation in normal surroundings.

Nursing diagnoses

u Anxiety u Fear u Impaired verbal communication u Ineffective individual coping u Knowledge deficit u Risk for infection u Risk for injury u Sensory or perceptual alterations

Key outcomes

- u The patient will remain free from signs and symptoms of infection.
- u The patient won't experience injury or harm.
- u The patient will express her needs and feelings.
- u The patient will regain hearing or develop alternative ways of communicating.
- u The patient and family members will express an understanding of the illness and treatment.

Nursing interventions

- u Address the patient's questions, encourage her to discuss her concerns about hearing loss, and offer reassurance when appropriate.
- u If the patient has difficulty understanding procedures because of hearing loss, give clear, concise explanations of treatments and procedures. Face her when speaking; enunciate clearly, slowly, and in a normal tone; and allow adequate time for her to grasp what you've said. Provide a pencil and paper to aid communication and alert the staff to her communication problem.
- u Follow the doctor's orders regarding specific postoperative positioning for the patient—on the unaffected side to prevent graft displacement or on the affected side to facilitate drainage. Some doctors allow any position that doesn't cause vertigo.
- u Assess for vertigo and assist with ambulation when indicated.
- u After surgery, keep the side rails of the bed up and help the patient walk.
- u Administer prescribed medication for pain and assess the patient's response. Meperidine may be given initially, followed by milder analgesics.

Patient teaching

- u For a patient undergoing surgery, provide preoperative and postoperative teaching. After surgery, advise her to move slowly to prevent vertigo.
- u Teach the proper administration of medications and possible adverse effects.
- u Stress the importance of protecting the ears against cold. Advise the patient to avoid any activities that provoke dizziness, such as straining, bending, or heavy lifting, and to avoid contact with anyone who has an upper respiratory tract infection.
- u Teach the patient and family members how to change the external ear dressing (eye or gauze pad) and care for the incision. Emphasize the need to complete the prescribed antibiotic regimen and to return for scheduled follow-up care, which includes removing the packing.
- u Point out that hearing may be masked by packing and dressing as well as swelling from the operation. Inform the patient that hearing may not be noticeably improved for 1 to 4 weeks after surgery.
- u Before discharge, instruct the patient to avoid loud noises and sudden pressure changes, such as those that occur while diving or flying, until healing is complete (usually within 6 months). Advise her against blowing her nose for at least 1 week to prevent contaminated air and bacteria from entering the eustachian tube.
- u Advise the patient to avoid sudden movements, which may result in dizziness. Also caution against wetting her head in the shower or swimming for about 6 weeks. Tell her to postpone washing her hair for 2 weeks and to avoid getting water in the ear for an additional 4 weeks.
- u Instruct the patient not to strain while defecating (Valsalva's maneuver) and to avoid constipation.

Inner ear disorders

Because the inner ear controls balance and hearing, disorders affecting it commonly produce loss of equilibrium, vertigo, nausea and vomiting, and hearing loss. Treatment varies with the disorder and may include drug therapy, surgery, and use of amplification devices.

HEARING LOSS

Hearing impairment is the most common disability in the United States and the third most prevalent in those over age 65. Mechanical or nervous impediment to the transmission of sound waves can produce hearing loss. The major forms are classified as conductive, sensorineural, or mixed.

In conductive hearing loss, sound is interrupted as it travels from the external canal to the inner ear (the junction of the stapes and the oval window). In sensorineural hearing loss, sound wave transmission is interrupted between the inner ear and the brain. The most common type of sensorineural hearing loss, presbycusis, is prevalent in adults over age 50 and can't be reversed or corrected. Mixed hearing loss combines dysfunction of conduction and sensorineural transmission.

Congenital hearing loss can be conductive or sensorineural. Premature or low-birth-weight infants with congenital hearing loss are most likely to have structural or functional hearing impairments; infants with serum bilirubin levels greater than 20 mg/dl also risk hearing impairment from the toxic effects of these high levels on the brain.

Effects of common ototoxic substances

Certain drugs and other substances can seriously damage the auditory function of the inner ear. Hearing loss from these substances can occur suddenly during short-term use or exposure or may be delayed.

The patient may notice only tinnitus, but audiometric tests show a progressive, high-tone, sensorineural hearing loss. If the patient has renal disease, the potential for ototoxicity increases.

The patient taking these drugs should report tinnitus, vertigo, or hearing loss immediately. Routine blood tests may be used to monitor the drug level in the patient's blood.

Common ototoxic substances include the following antibiotics, diuretics, and miscellaneous agents.

Antibiotics

Aminoglycosides, such as amikacin, gentamicin, kanamycin, neomycin, netilmicin, streptomycin, and tobramycin, can cause permanent hearing loss.

Other antibiotics that have the potential for ototoxicity include capreomycin, erythromycin, minocycline, polymyxin B, and vancomycin.

These antibiotics cause deafness by destroying the hair cells of the cochlea.

Diuretics

Ethacrynic acid and furosemide are ototoxic drugs. These diuretics affect the stria vascularis (the layer of fibrous tissue covering the cochlear duct). Inform the patient that discontinuing these drugs usually restores hearing.

Miscellaneous agents

Anticancer drugs, such as bleomycin, carmustine, and cisplatin; chloroquine; quinidine gluconate; quinine; and salicylates have toxic effects on the inner ear. Although their action isn't known, stopping these drugs usually restores hearing.

Poisons, such as arsenic, cadmium, disulfide, carbon monoxide, lead, mercury, and phosphorus, are also toxic to the inner ear. Poisons and other miscellaneous agents usually affect the nerve pathway. Hearing loss associated with these agents may be temporary or permanent.

Sudden hearing loss, which can occur in a patient with no previous hearing loss, can be conductive, sensorineural, or mixed and usually affects only one ear. Depending on the cause, prompt treatment (within 48 hours) may restore hearing.

Noise-induced hearing loss may be transient or permanent. Such hearing loss is common in workers subjected to constant industrial noise and in military personnel, hunters, and rock musicians.

Hearing loss may be partial or total and is calculated using the American Medical Association formula: Hearing is 1.5% impaired for every decibel (dB) that the pure tone average exceeds 25 dB.

Causes and pathophysiology

The most common cause of conductive hearing loss is cerumen (earwax) impaction, which occurs in patients with small or hairy ear canals. Conductive loss may be caused by anything that blocks the external ear (foreign body, edema, or drainage by infection) or by thickening, retraction, scarring, or perforation of the tympanic membrane. Other causes include otitis media, which is common in children and may accompany an upper respiratory tract infection; otitis externa, which results from a gram-negative bacterial infection of the external ear canal; and otosclerosis, which produces ossification of the stapedioves-tibular joint.

Sensorineural hearing loss is caused by impairment of the cochlea and eighth cranial or acoustic nerve. The most common form of this type of hearing loss, presbycusis, results from loss of hair cells and nerve fibers in the cochlea or from drug toxicity. Other causes of "nerve deafness" are infectious diseases (measles, mumps, meningitis), arteriosclerosis, otospongiosis, injury to the head or ear, or degeneration of the organ of Corti. Sensorineural hearing loss may also follow prolonged exposure to loud noise (85 to 90 dB) or brief exposure to extremely loud noise (greater than 90 dB). Occasionally, sensorineural hearing loss results from an acoustic neuroma (a benign tumor that can be life-threatening).

Congenital hearing loss, which may be sensorineural or conductive, may be transmitted as a dominant, autosomal dominant, autosomal recessive, or sex-linked recessive trait. Hearing loss in neonates may also result from trauma, toxicity, or infection during pregnancy or delivery.

Predisposing factors include a family history of hearing loss or known hereditary disorders (for example, otosclerosis), maternal exposure to rubella or syphilis during pregnancy, use of ototoxic drugs during pregnancy, prolonged fetal anoxia during delivery, and congenital abnormalities of the ears, nose, or throat. In addition, trauma during delivery may cause intracranial hemorrhage and damage the cochlea or acoustic nerve.

The cause of sudden hearing loss is unknown. However, the possibilities include occlusion of the internal auditory artery by spasm or thrombosis, subclinical mumps and other bacterial and viral infections, acoustic neuroma, or a single episode of Ménière's disease.

Sudden hearing loss also may be caused by metabolic disorders, such as hypothyroidism, diabetes mellitus, and hyperlipoproteinemia; vascular disorders such as hypertensive arteriosclerosis; neurologic disorders, such as multiple sclerosis and neurosyphilis; blood dyscrasias, such as leukemia and hypercoagulation; and ototoxic drugs, such as tobramycin, streptomycin, quinine, gentamicin, furosemide, and ethacrynic acid. (See [Effects of common ototoxic substances.](#))

Complications

If untreated, conductive hearing loss resulting from otitis media can lead to tympanic membrane perforation, cholesteatoma, and permanent hearing loss.

Assessment findings

Although congenital hearing loss may produce no obvious signs of hearing impairment at birth, the infant generally demonstrates deficient response to auditory stimuli within 2 to 3 days. In an older child, the patient history may describe a hearing loss that impairs speech development. Rinne and Weber's tests may indicate if the hearing loss is conductive or sensorineural.

In conductive hearing loss, the history may uncover a recent upper respiratory tract infection. Weber's test is positive, and the Rinne test also may be positive (a positive Rinne test also may indicate sensorineural hearing loss).

A patient with sudden deafness may report recent exposure to loud noise or brief exposure to an extremely loud noise. The patient may complain of persistent tinnitus and transient vertigo. Audiometric tests indicate that the patient has a loss of perception of certain frequencies (around 4,000 Hz) or, if he's experienced lengthy exposure, loss of perception of all frequencies. Weber's and Rinne tests may indicate conductive or sensorineural hearing loss.

In sensorineural hearing loss due to presbycusis, the patient history is probably the most valuable assessment tool because the patient may not have noticed the hearing loss or may deny it. The history also may expose the use of ototoxic substances. Hearing tests reveal a loss that is usually in the high-frequency tones. The

patient may report a history of tinnitus. A positive Rinne test may indicate sensorineural hearing loss. (See [Detecting hearing loss.](#))

ADVANCED PRACTICE

Detecting hearing loss

As you take a history, question the patient and his family about the following signs and symptoms of hearing loss.

In adults

Signs of conductive or sensorineural hearing loss include:

- inattentiveness
- inappropriate responses to questions or environmental sounds
- irrelevant comments
- requests for the speaker to repeat statements
- cocking one ear toward sound
- unusually loud speech or unusual voice quality.

Other signs and symptoms of sensorineural hearing loss are:

- diminished ability to hear high-pitched voices
- hypersensitivity to loud sounds
- tinnitus
- difficulty discriminating between speech and background noise
- inability to follow or participate adequately in a conversation.

In toddlers

Signs of hearing loss include:

- failure to talk clearly by age 2
- habitual yelling or shrieking when playing or communicating
- greater response to facial expressions than to speech
- shyness or withdrawal; preference for playing alone over socializing
- inattentiveness, dreaminess, or stubbornness
- air of confusion or puzzlement
- disinterest in reading or playing word games.

In infants

Signs of hearing loss include:

- failure to blink or startle at a loud noise
- sleeping through a loud noise
- failure to turn the head toward familiar sounds
- greater response to loud noises than to voices
- failure to babble, coo, or squeal often or in response to a voice; monotone babbling.

Diagnostic tests

Auditory brain response is used to measure activity in the auditory nerve and brain stem. If the test results are positive or inconclusive, additional tests may be ordered.

A computed tomography scan helps to evaluate vestibular and auditory pathways, and pure tone audiometry is used to assess the presence and degree of hearing loss.

Magnetic resonance imaging is used to evaluate brain condition and helps detect acoustic tumors or lesions. Electronystagmography is used to evaluate vestibular function.

Otoscopic or microscopic examination can be used to diagnose middle ear disorders or remove debris of infection.

Treatment

Treatment for patients with hearing loss varies with the type and cause of impairment and may include medication to treat infections and dissolve cerumen, surgery (stapedectomy, tympanoplasty, cochlear implant, and myringotomy), hearing aids or other effective means of aiding communication, and antibiotics and decongestants for hearing loss due to otitis media. Analgesics may be given for pain. Antipyretics may be given for fever. Sedatives may be given to small children for comfort.

Treatment for sudden deafness requires prompt identification of the underlying cause.

For noise-induced hearing loss, overnight rest usually restores normal hearing in the patient exposed to noise levels greater than 90 dB for several hours but who hasn't been exposed to such noise repeatedly. As hearing deteriorates, treatment should include speech and hearing rehabilitation because hearing aids rarely help.

Presbycusis may necessitate a hearing aid.

Dietary measures can help to prevent further hearing loss. Studies suggest that people with high cholesterol levels have greater hearing loss as they age than people with low cholesterol levels.

Nursing diagnoses

▫ Altered nutrition: More than body requirements ▫ Anxiety ▫ Fear ▫ Impaired verbal communication ▫ Ineffective individual coping ▫ Knowledge deficit ▫ Pain ▫ Risk for infection ▫ Risk for injury ▫ Self-esteem disturbance ▫ Sensory or perceptual alterations

Key outcomes

- u The patient will express feelings of comfort.
- u The patient and family members will express an understanding of the condition and treatment.
- u The patient won't experience injury or harm.
- u The patient will express his feelings about the disorder and exhibit adequate coping mechanisms.
- u The patient will regain hearing or develop alternate means of communication.

Nursing interventions

- u Answer the patient's questions, encourage him to discuss his concerns about hearing loss, and offer reassurance when appropriate.
- u If the patient has difficulty understanding procedures because of hearing loss, give clear, concise explanations of treatments and procedures. Face him when speaking; enunciate words clearly, slowly, and in a normal tone; and allow adequate time for him to grasp what is expected. Provide a pencil and paper to aid communication and alert the staff to his communication problem.
- u To speak to a patient who can read lips, approach within his visual range and attract his attention by raising your arm or waving. (Touching him may be unnecessarily startling.) Then stand directly in front of him in a well lit area and speak slowly and distinctly.
- u Place the patient with hearing loss in a place where he can observe activities and approach people because such a patient depends totally on visual clues.
- u Encourage the patient who's learning to use a hearing aid because he may experience periods of self-doubt and apprehension about wearing the aid.
- u Refer children with suspected hearing loss to an audiologist or otolaryngologist for further evaluation.

Patient teaching

- u Teach the patient and family members about hearing loss, its causes, and treatments.
- u Explain all tests and procedures. For the patient who requires surgery, give preoperative and postoperative instructions.
- u For the patient receiving a hearing aid, demonstrate how to operate and maintain the device and suggest carrying extra batteries at all times. Remind him that the aid won't restore hearing to a normal level and that it makes speech louder but not necessarily clearer. Encourage him to experiment with the controls for best results. Advise him that lessons in lip-reading may increase the effectiveness of the aid. Tell him that if the hearing aid requires repair, he may be able to borrow one from the repair agency.
- u For the patient with temporary hearing loss, emphasize the danger of excessive exposure to noise and encourage the use of protective devices in a noisy environment.
- u If the patient is pregnant, stress the danger of exposure to drugs, chemicals, and infection (especially rubella).
- u Encourage the patient to maintain a low-cholesterol diet and teach him about foods that are low in cholesterol.
- u If the patient's hearing loss stems from cerumen buildup and the doctor has advised ear cleaning or irrigation, demonstrate the proper technique for this and for instilling medication.
- u If the patient has hearing loss due to otitis media, discuss the antibiotics and decongestants ordered and tell him to report any adverse effects.
- u Review the ordered medication, its proper dosage, administration, and possible adverse effects.
- u Encourage the patient to tell the doctor about any significant earache.

LABYRINTHITIS

Labyrinthitis is an inflammation of the labyrinth of the inner ear (which controls both hearing and balance). Labyrinthitis typically produces severe vertigo with head movement and sensorineural hearing loss. Vertigo begins gradually but peaks within 48 hours. Because it may last 3 to 5 days, causing loss of balance and falling in the direction of the affected ear, it often incapacitates the patient. Symptoms gradually subside over 3 to 6 weeks. Prevention is possible through early and vigorous treatment of predisposing conditions, such as otitis media and any local or systemic infection.

Causes

Labyrinthitis results from the same organisms (viral or bacterial infections) that cause acute febrile diseases, such as pneumonia, influenza and, especially, chronic otitis media. Viral labyrinthitis—the most prevalent form—may result from measles, mumps, rubella, or encephalitis. Bacterial labyrinthitis may be caused by otitis media infection or bacterial meningitis. In chronic otitis media, cholesteatoma formation erodes the labyrinth bone, allowing bacteria to enter from the middle ear. Drug toxicity also may cause labyrinthitis.

Complications

Meningitis may develop as well as partial or total hearing loss on the affected side, trauma from falling, permanent balance disability, and decreased quality of life.

Assessment findings

The patient with labyrinthitis may complain of severe vertigo from any movement of the head, nausea and vomiting, and a unilateral or bilateral hearing loss. Questioning may uncover a recent upper respiratory tract infection. Tinnitus may not be present.

On inspection, note spontaneous nystagmus, with jerking movements of the eyes toward the unaffected ear. The patient may also demonstrate excessive giddiness. To minimize these symptoms, he may assume a characteristic posture—lying on the side of the unaffected ear and looking in the direction of the affected ear. Examination of the affected ear may reveal purulent drainage.

Diagnostic tests

Evaluation of labyrinthitis relies on culture and sensitivity tests to identify the infecting organism if purulent drainage is present, audiometric testing to reveal any sensorineural hearing loss, computed tomography scanning to rule out a brain lesion, and tympanometry and electronystagmography.

Treatment

Treatment measures are based on relieving the patient's symptoms and include bed rest with the head immobilized between pillows, meclizine given orally to relieve vertigo, and massive doses of antibiotics to combat diffuse purulent labyrinthitis. Oral fluids can prevent dehydration from vomiting; I.V. fluids may be needed for severe nausea and vomiting.

When conservative management fails, treatment necessitates surgical excision of the cholesteatoma and drainage of the infected areas of the middle and inner ear. A labyrinthectomy or vestibular nerve section may be done in some patients.

Nursing diagnoses

- u Activity intolerance u Anxiety u Fear u Knowledge deficit u Risk for fluid volume deficit u Risk for infection u Risk for injury u Sensory or perceptual alterations

HOME CARE

Managing labyrinthitis

- u Tell the patient to avoid sudden position changes.
- u Help the patient assess how much this disability will affect his daily life.
- u Work with the patient to identify hazards in the home (such as throw rugs and dark stairways).
- u Discuss the patient's anxieties and concerns about vertigo attacks and decreased hearing.
- u Stress the importance of maintaining and resuming normal diversions or social activities when balance disturbance is absent.

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will maintain normal fluid volumes.
- u The patient will remain free from signs and symptoms of infection.
- u The patient won't experience injury or harm.
- u The patient will verbalize an understanding of the condition and treatment.

Nursing interventions

- u Answer the patient's questions, encourage him to express his concerns about hearing loss, and offer reassurance when appropriate.
- u If the patient has difficulty understanding procedures because of hearing loss, give clear, concise explanations of treatments and procedures. Face him when speaking; enunciate words clearly, slowly, and in a normal tone; and allow adequate time for him to grasp what is expected. Provide a pencil and paper to aid communication and alert the staff to his communication problem.
- u Keep the side rails of the bed up to ensure the patient's safety. Assist with ambulation as needed to prevent falls.
- u Maintain the patient on bed rest in a darkened room with his head immobile to reduce symptoms.
- u Give antiemetics as ordered and monitor the patient's response.
- u Monitor blood pressure, turgor, mucous membranes, and pulse for symptoms of dehydration. Provide the patient with oral fluids to prevent dehydration from vomiting. If vomiting precludes oral intake, administer I.V. fluids as ordered and monitor the patient's intake and output.

Patient teaching

- u Review the disease process and what can be done to treat and prevent its occurrence.
- u Caution the patient to limit activities, such as driving a motor vehicle or operating machinery, to avoid danger from vertigo.
- u Reassure the patient that recovery is certain but may take as long as 6 weeks. Review the home care checklist. (See [Managing labyrinthitis.](#))
- u Encourage the patient to seek prompt treatment for upper respiratory tract and systemic infections, particularly for otitis media.
- u Stress the importance of controlling the use of salicylates and other potentially toxic substances.
- u Instruct the patient to complete the medication regimen as prescribed. Warn him to discontinue the drug and notify the doctor if any adverse effects occur.
- u If surgery is required, give the patient preoperative and postoperative instructions.

MÉNIÈRE'S DISEASE

Ménière's disease (endolymphatic hydrops) is an inner ear problem stemming from a labyrinthine dysfunction. It's associated with increased fluid pressure within the labyrinth. Although it usually affects adults between ages 30 and 60, it may begin at any age. It occurs in both sexes.

The disease involves only one ear at first, but about 20% of patients eventually develop problems in both ears. Even with proper treatment, this chronic disease can cause hearing loss.

Causes and pathophysiology

Ménière's disease may result from an overproduction or decreased absorption of endolymph, the fluid within the cochlea and semicircular canals. Pressure from this excess fluid disturbs and damages the sensory cells that transmit hearing and balance perception to the brain. (See [Understanding Ménière's disease.](#))

The cause of this overproduction (or underabsorption) is unknown. Various theories attribute the problem to excess sodium retention, an allergic reaction to certain foods, vascular spasms that constrict blood vessels supplying the inner ear, or metabolic, toxic, and emotional factors. These factors may influence the interval of an attack or precipitate an attack.

Complications

This disorder leads to residual tinnitus and partial to total hearing loss on the affected side, permanent balance disability, trauma from falling, dehydration, and reduced quality of life.

Assessment findings

In taking the patient's history, note the cardinal symptom of Ménière's disease: vertigo. The patient may complain that the symptom has a sudden onset and lasts up to several hours. If the disorder has progressed, the patient may relate that attacks occur more frequently, as often as every 2 or 3 days. The dizziness may be so severe that the patient loses his balance and falls to the affected side.

The patient may also complain about tinnitus that occurs as a low, fluctuating buzzing, hissing, or humming sound in the ear that is often louder before and during an attack; this may be the only symptom the patient notices between attacks. He may report a distortion in sound, hearing loss, and a feeling of pressure or fullness in the affected ear.

Between attacks, the patient may be free of vertigo. The patient may experience imbalance, unsteady gait, history of falls, inability to maintain an upright position or posture, inability to walk heel to toe on examination, visual changes (blurred vision, diplopia), altered taste or smell, and altered communication. In addition, findings may include hypotension, vomiting or diarrhea, changes in lifestyle, withdrawal, depression, fear, anxiety, and panic. Because these signs can mimic other disorders, diagnostic tests must be performed to confirm the diagnosis.

Diagnostic tests

Electronystagmography is used to measure the electropotential of eye movements when nystagmus is produced and provides a graphic recording of labyrinthine function.

Audiometric tests reveal sensorineural loss and loss of discrimination and recruitment. An auditory brain stem response test helps determine if a cochlear or retrocochlear lesion is causing hearing loss.

Magnetic resonance imaging is used to evaluate the structure of the brain and rules out brain lesions or tumors. Laboratory testing must be done to rule out metabolic

problems (hypoglycemia or thyroid, lipid, or autoimmune disorders).

PATHOPHYSIOLOGY

Understanding Ménière's disease

In a person with normal hearing, the inner ear's two fluid-filled structures make hearing possible and maintain balance. The snail-shaped cochlea transduces sound waves into nerve impulses, which then continue on to the brain. The loop-shaped semicircular canals detect changes in balance and body orientation. Together, these structures form the labyrinth, named for its complicated twists, bends, and turns.

INNER EAR WITH NORMAL FLUID PRESSURE

In Ménière's disease, the fluid pressure in the labyrinth increases, perhaps because of an overproduction or underabsorption of fluid. The resultant swelling causes hearing loss, dizziness, and related symptoms.

INNER EAR WITH INCREASED FLUID PRESSURE

Treatment

Management of Ménière's disease aims to eliminate vertigo and prevent further hearing loss. For an acute attack, the patient may assume whatever position is comfortable. Atropine may stop the attack in 20 to 30 minutes. Dimenhydrinate, meclizine, diphenhydramine, or diazepam may relieve a mild attack. A severe attack may respond to epinephrine or diphenhydramine.

Long-term management includes the use of diuretics or vasodilators, vestibular suppressants, labyrinthine exercises, and restricted sodium intake. Prophylactic antihistamines or mild sedatives may also help. Three-fourths of patients respond to a salt-free diet and the use of diuretics. However, diuretic efficacy hasn't been proven. Avoiding tobacco, alcohol, and caffeine may be recommended. In the anxious and fearful or depressed patient, a psychological evaluation is indicated.

If disease persists after more than 2 years of treatment or produces incapacitating vertigo, the patient may require surgery. Some patients benefit from endolymphatic sac decompression (endolymphatic shunt). This procedure creates an opening in the labyrinth to drain excess fluid from the ear. A more complex procedure resects the vestibular nerve, which carries impulses from the mechanisms involved with position sense in the inner ear to the brain. If the patient has severe hearing loss in one ear, radical labyrinthectomy may be helpful.

Nursing diagnoses

- u Altered nutrition: More than body requirements
- u Anxiety
- u Fear
- u Fluid volume deficit
- u Hopelessness
- u Ineffective individual coping
- u Knowledge deficit
- u Powerlessness
- u Risk for injury
- u Sensory or perceptual alterations

Key outcomes

- u The patient will express feelings of comfort.
- u The patient won't experience injury or harm.
- u The patient will maintain adequate fluid balance.
- u The patient will regain hearing or develop alternate means of communication.
- u The patient and family members will seek appropriate support groups to assist with coping.

Nursing interventions

- u If the patient experiences an attack in the facility, keep the bed rails up to prevent falls. Don't let the patient rise or walk without help.
- u Answer the patient's questions, encourage him to express his concerns about hearing loss, and offer reassurance when appropriate.
- u If the patient has difficulty understanding procedures because of hearing loss, give clear, concise explanations of treatments and procedures. Face him when speaking; enunciate words clearly, slowly, and in a normal tone; and allow adequate time for him to grasp what is expected. Provide a pencil and paper to aid communication and alert the staff to his communication problem.

- u Before surgery, if the patient is vomiting, record fluid intake and output and characteristics of emesis. Administer antiemetics as ordered and give small amounts of fluid frequently.
- u After surgery, record intake and output carefully.
- u Give prophylactic antibiotics and antiemetics as ordered and monitor the patient's response.
- u Help the patient to identify successful coping behaviors.
- u Teach the patient about the diagnosis and treatment.
- u Stress the importance of maintaining his activity level and including regular exercise in his schedule.

Patient teaching

- u Review a low-sodium diet with the patient. Discuss foods and nonprescription medications that contain sodium.
- u Instruct the patient about prescribed diuretics and vasodilators. Tell him to report any adverse effects.
- u Advise against reading and exposure to glaring lights to reduce dizziness.
- u Instruct the patient to avoid sudden position changes and any tasks that vertigo makes hazardous because an attack can begin rapidly.
- u Because stress and fatigue can trigger attacks, teach the patient relaxation and stress management techniques. Review ways to modify the patient's lifestyle, including making adequate time for rest and relaxation.

After surgery:

- u Tell the patient to expect dizziness and nausea for 1 to 2 days.
- u Because Bell's palsy is a complication of surgery, instruct the patient to be alert for possible signs, such as facial numbness and tingling and incomplete eye closure.

Nasal disorders

Although seldom life-threatening, disorders of the nose can severely impair breathing and occasionally cause serious complications. Many nasal disorders are more common in children than adults. Treatment includes drug therapy, surgery, and measures to control bleeding and improve breathing.

ADENOID HYPERPLASIA

Adenoid hyperplasia (adenoid hypertrophy) is enlargement of the lymphoid tissue of the nasopharynx. It's a fairly common childhood condition. Normally, adenoidal tissue is small at birth (⅜" to ¼" [20 to 32 m]), grows until the child reaches adolescence, and then slowly begins to atrophy. In adenoid hyperplasia, this tissue continues to grow.

Causes

The precise cause of adenoid hyperplasia is unknown. Contributing factors may include heredity, repeated infection, chronic nasal congestion, persistent allergy, insufficient aeration, and inefficient nasal breathing. Inflammation resulting from repeated infection increases the patient's risk of respiratory obstruction.

Complications

Adenoid hyperplasia can obstruct the eustachian tube and predispose the patient to otitis media, which in turn can lead to fluctuating conductive hearing loss. Stasis of nasal secretions from adenoidal inflammation can lead to sinusitis, right-sided heart failure, and cor pulmonale.

Adenoid hyperplasia in children may cause sleep apnea, transient breathing difficulties that may result in acidosis, and pulmonary arterial hypertension.

Assessment findings

Typically, adenoid hyperplasia produces symptoms of respiratory obstruction. Parents may report that the child breathes through the mouth; snores at night; experiences frequent, prolonged nasal congestion; and has a history of chronic otitis media with some hearing loss. Sleep apnea, rhinorrhea, daytime sleepiness, fatigue, fever, and nasal discharge are also common. The child may mention a decrease in appetite due to alteration in taste and smell.

Inspection confirms mouth breathing. The child's voice may sound nasal and muffled. You may also detect foul breath and dry oral mucous membranes. If the child experienced persistent mouth breathing during the formative years, inspection may show distinctive facial features changes, including a slightly elongated face, open mouth, highly arched palate, shortened upper lip, and vacant expression. Signs of nocturnal respiratory insufficiency may be apparent, including intercostal retractions and nasal flaring.

Cervical posterior lymph nodes may feel enlarged on palpation.

Diagnostic tests

Nasopharyngoscopic or rhinoscopic visualization of abnormal tissue mass confirms adenoid hyperplasia. X-rays (lateral pharyngeal films) show obliteration of the nasopharyngeal air column and lymphoid hypertrophy.

Treatment

Antibiotics initially may be used for recurring infection of the adenoids and adenoid hypertrophy. If medical management isn't effective, surgery is indicated. Adenoidectomy, the treatment of choice for adenoid hyperplasia, commonly is recommended for the patient with recurrent or prolonged mouth breathing, nasal speech, adenoid facies, recurrent otitis media, constant nasopharyngitis, and nocturnal respiratory distress. This procedure usually eliminates recurrent nasal infections and ear complications and reverses secondary hearing loss.

Adenoidectomy should be performed in conjunction with tympanotomy tube placement when the adenoidal hypertrophy contributes to ear disorders. Antibiotics may be used to treat infection. Decongestants may be used to decrease edema.

Nursing diagnoses

- u Anxiety u Fatigue u Fear u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for aspiration u Risk for infection

Key outcomes

- u The patient will verbalize feelings about the condition.
- u The patient will exhibit adequate breathing patterns.
- u The patient will express feelings of comfort.

WARNING

Assessing for bleeding

After adenoidectomy, bleeding can be a serious complication. To assess the patient for bleeding, frequently check the throat for blood and observe for continuous swallowing of blood. While the patient is asleep, note the frequency of swallowing. Be alert for vomiting of old, partially digested blood (coffee-ground vomitus). If bleeding persists, notify the doctor immediately.

- u The patient won't show signs of aspiration.
- u The patient will express an understanding of the condition and treatment.

Nursing interventions

- u Answer questions from the patient and family members, encourage them to express their concerns, and stay with the patient during anxious periods. Include the patient and family members in all phases of care.
- u Elevate the head of the bed to minimize edema and increase humidification for comfort.

After surgery:

- u Maintain a patent airway. Position the child on his side, with his head down, to prevent aspiration of draining secretions. Frequently assess the child for bleeding. (See [Assessing for bleeding.](#))
- u Closely monitor vital signs and report excessive bleeding, an increase in pulse rate, a decrease in blood pressure, tachypnea, restlessness, and a fever higher than 101° F (38.3° C).
- u If no bleeding occurs, offer ice chips or water when the patient is fully awake.
- u Provide analgesics for pain relief. Because crying can irritate the operative site, keep the child comfortable.
- u Keep suction equipment at the bedside.

Patient teaching

- u Before surgery, describe the facility's routine and arrange for the child and parents to tour relevant areas.
- u Explain adenoidectomy to the child and family members, using illustrations if necessary. Detail the recovery process. Explain that surgery may be performed on an outpatient basis with about 6 hours of postoperative observation, provided no complications require inpatient hospitalization. Tell them that the child's voice may sound nasal temporarily after surgery.
- u After surgery, discuss normal postoperative findings, including halitosis, low-grade fever, and a slight earache. Tell the patient and family members that a heating pad may be used for local comfort.
- u Review signs and symptoms of bleeding and teach family members how to assess the child for possible bleeding.
- u Because of the risk for right-sided heart failure and cor pulmonale, teach family members to monitor for and report signs and symptoms.
- u Discuss signs and symptoms that require medical intervention, including severe earache, fever higher than 101° F, or cough.
- u Emphasize the importance of not smoking and of avoiding aspirin.
- u Instruct the patient to finish antibiotics and medications as ordered.

CLEFT LIP AND PALATE

Cleft lip and palate deformities originate in the second month of gestation when the front and sides of the face and the palatine shelves fuse imperfectly. They fall into four categories: clefts of the lip (unilateral or bilateral); clefts of the palate (along the midline); unilateral clefts of the lip, alveolus (gum pad), and palate (twice as common on the left side as the right); and bilateral clefts of the lip, alveolus, and palate. Another cleft disorder, Pierre Robin syndrome, occurs when micrognathia and glossoptosis coexist with cleft palate.

CULTURAL TIP Cleft lip and cleft palate are most common in Asians and Native Americans and least common in blacks. Cleft lip with or without cleft palate is more common in males. Cleft palate alone is more common in females.

Because the palate is essential to speech, structural changes—even in a repaired cleft—can permanently affect speech patterns. Children with cleft palates commonly experience hearing difficulties because of middle ear damage or infection. Early treatment preserves speech and language formation and swallowing.

Causes

Cleft lip and palate are genetic, resulting from multifactorial (polygenic) errors. (See [How cleft lip and palate develop.](#))

PATHOPHYSIOLOGY

How cleft lip and palate develop

Although cleft lip and cleft palate are common birth defects, their precise cause is unknown.

Cleft lip

Cleft lip occurs around the 7th week of gestation. Normal fetal development at 5 weeks shows two horseshoe-shaped swellings on each side of the face (as shown in the 5th-week illustration). By 7 weeks' gestation, these swellings slowly move toward the middle of the face (7th-week illustration). When this fusion doesn't take place, a cleft lip results. Eventually (around 9 weeks' gestation) these swellings form the nostrils. Tissue just below the nostrils also moves together to form the upper lip (12th-week illustration).

Cleft palate

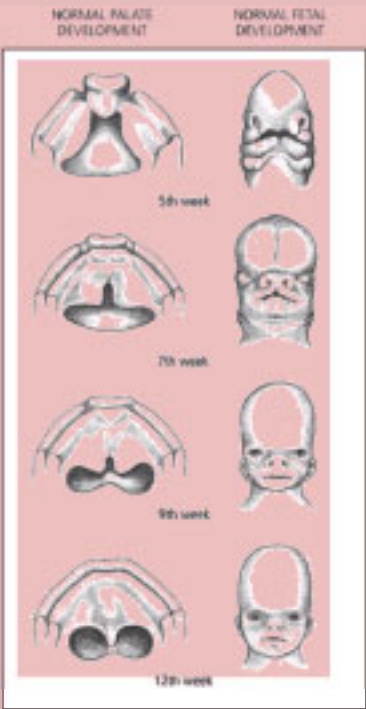

Cleft palate may occur a few weeks later in gestation. As the neck and jaws of the fetus take form, the tongue separates the two sides of the palate. Normally, the tongue moves downward and the two sides of the secondary palate fuse together above it. If this movement is delayed or the tongue doesn't descend, the palate doesn't fuse.

Various manifestations

Because the lip and the palate develop separately, a child can have a cleft lip, a cleft palate, or both.

Clefts of the lip can appear on one side of a child's mouth (unilateral) or on both sides (bilateral). The severity varies; the cleft may involve only the vermilion (darkened) tissue of the lip, or it may extend into the nose.

Cleft palate also varies in severity. It may affect only the uvula and the soft palate (the rear of the mouth), or it may extend from the soft palate into the hard palate. A cleft that stretches into only one nasal cavity is called a unilateral cleft palate; a bilateral cleft palate affects both nasal cavities.

Complications

Speech difficulties and failure to thrive (due to inadequate oral intake) are possible complications of nonrepaired clefts. In addition, dentition problems, increased episodes of otitis media, hearing defects, and appearance are concerns.

Assessment findings

Inspection findings range from a simple notch to a complete cleft that extends from the lip through the floor of the nostril on either side of the midline. A cleft palate may be partial or complete; if complete, inspection may show involvement of the soft palate, the bones of the maxilla, and the alveolus on one or both sides of the premaxilla.

In a double cleft, the most severe of all cleft deformities, inspection may disclose a cleft that runs from the soft palate forward to either side of the nose, separating the maxilla and the premaxilla into free-moving segments. The tongue and other muscles can displace these segments, enlarging the cleft.

Diagnostic tests

No specific tests exist for cleft lip and palate.

Treatment

Cleft deformities must be treated with a combination of speech therapy and surgery. The timing of surgery varies. Some plastic surgeons repair cleft lips within a few days of life to make feeding the baby easier. Many surgeons delay lip repairs for 8 to 10 weeks (sometimes as long as 6 to 8 months) to allow time for maternal bonding and, most important, to rule out associated congenital anomalies.

Cleft palate repair is usually completed by the 12th to 18th month. Some surgeons repair cleft palates in two steps, repairing the soft palate between ages 6 and 18 months and the hard palate as late as age 5 years. In any case, surgery is performed only after the infant is gaining weight and is infection-free.

Surgery must be coupled with speech therapy. Because the palate is essential to speech formation, structural changes, even in a repaired cleft, can permanently affect speech patterns. To compound the problem, children with cleft palates often have hearing difficulties because of middle ear damage or infections.

Nursing diagnoses

⌞ Altered nutrition: Less than body requirements ⌞ Anxiety ⌞ Body image disturbance ⌞ Fear ⌞ Impaired swallowing ⌞ Knowledge deficit ⌞ Risk for altered development ⌞ Risk for altered growth ⌞ Risk for altered parent/infant/child attachment ⌞ Risk for aspiration ⌞ Risk for injury ⌞ Self-esteem disturbance

Key outcomes

- ⌞ The patient and family members will express an understanding of the condition and treatment.
- ⌞ The patient won't aspirate.
- ⌞ The patient will exhibit normal growth and development patterns within the confines of the disorder.
- ⌞ The patient and family members will seek appropriate resources to assist with coping.

Nursing interventions

- u The parents of a neonate with cleft lip or palate often feel shock, disappointment, and guilt when they first see their baby. Help them by staying calm and directing their attention to their child's assets, emphasizing what is “right” about the baby. To encourage normal bonding, immediately include them in the infant's care and feeding. Answer their questions, encourage them to express their concerns, and stay with them during anxious periods. Refer them to a social worker who can guide them to community resources.
- u Never place the infant with Pierre Robin syndrome on his back because the tongue can fall back and obstruct the airway. Train such an infant to sleep on one side. All other infants with cleft palate can sleep on their backs without difficulty.
- u Maintain adequate nutrition for normal growth and development. Experiment with feeding devices. An infant with cleft palate has an excellent appetite, but he often has trouble feeding because of nasal regurgitation and air leaks around the cleft. Usually, such an infant feeds better from a nipple with a flange that occludes the cleft, a lamb's nipple (a big, soft nipple with large holes), or a regular nipple with enlarged holes.

After surgery:

- u Restrain the infant to prevent self-injury. Elbow restraints allow the infant to move his hands while keeping them away from the mouth. When necessary, use an infant seat to keep the infant in a comfortable position. Hang toys within reach of his restricted hands.
- u If the doctor has placed a curved metal Logan bow over a repaired cleft lip to minimize tension on the suture line, check the facility's policy about follow-up care. You may need to remove the gauze before feedings, replace it frequently, and moisten it with normal saline solution until the sutures are removed.

Patient teaching

- u Stress to parents that surgery can be done to repair the cleft. Provide instructions so they can take proper care of the infant at home.
- u Encourage the mother of an infant with cleft lip to breast-feed if the cleft doesn't impede effective sucking. Tell the mother of an infant who has cleft palate or has just had corrective surgery that breast-feeding is most likely impossible for up to 6 weeks. However, if the mother desires, suggest that she use a breast pump to express her milk for bottle feedings.
- u Teach the mother to hold the infant in a near-sitting position when feeding to prevent choking and aspiration, with the flow directed to the side or back of the infant's tongue. Tell her to burp the infant frequently because he may tend to swallow a lot of air.

NASAL PAPILLOMAS

A nasal papilloma is a benign epithelial tissue overgrowth within the intranasal mucosa. It may be inverted or exophytic. Inverted papillomas grow into the underlying tissue, usually at the junction of the antrum and the ethmoid sinus; they generally occur unilaterally and sometimes are associated with squamous cell carcinoma. Exophytic papillomas, which tend to occur singly, arise from epithelial tissue, commonly on the surface of the nasal septum. Both types are most prevalent in males. Recurrence is likely, even after surgical excision.

Causes

A papilloma may arise as a benign precursor of a neoplasm or as a response to tissue injury or viral infection, but its cause is unknown. These tumors usually originate from the lateral nasal wall but may involve the ethmoid and maxillary sinuses and may undergo malignant transformation if left untreated.

Complications

Rarely, nasal papillomas result in severe respiratory distress, nasal drainage, and infection.

Assessment findings

The patient with inverted or exophytic papillomas typically complains of unilateral nasal stuffiness, postnasal drip, headache, shortness of breath, dyspnea and, occasionally, with exophytic papillomas, epistaxis. The patient may also have a history of nasal polyps, nasal polypectomy, or polypoid masses.

With inverted papillomas, inspection of the nasal mucosa usually reveals large lesions that are bulky, highly vascular, and edematous, with a color and consistency that varies from dark red to gray and firm to friable. Exophytic papillomas are commonly raised, firm, rubbery, and pink to gray in color. They're securely attached to the mucous membrane by a broad or pedunculated base.

Diagnostic tests

Tissue biopsy for histologic examination is used to confirm the diagnosis. A computed tomography scan shows bone destruction or erosion.

Treatment

The most effective treatment is wide surgical excision or diathermy with careful inspection of adjacent tissues and sinuses to rule out extension. Aspirin or acetaminophen and decongestants may relieve symptoms.

Nursing diagnoses

- u Altered oral mucous membrane
- u Anxiety
- u Fear
- u Ineffective breathing pattern
- u Knowledge deficit
- u Risk for injury

Key outcomes

- u The patient will express his concerns about the condition.
- u The patient will exhibit adequate breathing patterns.
- u The patient won't experience injury or harm.
- u The patient will express an understanding of the condition and treatment.
- u The patient will avoid complications.

Nursing interventions

- u Answer the patient's questions, encourage him to express concerns, and stay with him during anxious periods. Include the patient and family members in all phases of care.
- u If bleeding occurs, raise the head of the bed and have the patient expectorate blood into an emesis basin. Compress the sides of the nose against the septum for 10 to 15 hours and, if necessary, apply ice compresses to the nose.
- u Check for airway obstruction by placing your hand under the patient's nostrils or use a mirror to assess air exchange. Watch for signs of mild shortness of breath.

After surgery:

- u Monitor vital signs and respiratory status. Monitor for early signs of infection (elevated white blood cell count, rising temperature).
- u As needed, administer analgesics and monitor the patient's response. Teach relaxation techniques to help control pain.
- u Because the patient with nasal packing is unable to breathe through the nose, provide frequent and meticulous mouth care.
- u To reduce or prevent edema and promote drainage, place the patient in semi-Fowler's position and use a cool-mist vaporizer to liquefy secretions and facilitate

normal breathing. To reduce facial edema and pain, place crushed ice in a rubber glove or a small ice bag and apply the glove or ice bag intermittently over the eyes and nose for 24 hours.

u To ensure proper absorption of drainage, frequently change the mustache dressing or drip pad, recording the type and amount of drainage. While the nasal packing is in place, expect scant, usually bright-red drainage that contains some clots. Remember that the amount of drainage often increases for a few hours after the packing is removed.

Patient teaching

- u If surgery is scheduled, review what to expect postoperatively: that nostrils probably will be packed and that it will be necessary to breathe through the mouth. Instruct the patient not to blow his nose. (Packing usually is removed 12 to 24 min after surgery.)
- u Because papillomas tend to recur, tell the patient to seek medical attention at the first sign of nasal discomfort, discharge, or congestion that doesn't subside with conservative treatment.
- u Encourage regular follow-up visits to detect early signs of recurrence or signs of infection (elevated temperature, increased drainage, foul odor), bleeding, or change in the level of pain.
- u Provide information about support groups and encourage participation in them.

NASAL POLYPS

Nasal polyps are benign and edematous growths that usually are multiple, mobile, and bilateral. They may become large and numerous enough to cause nasal distention and enlargement of the bony framework, possibly occluding the airway. Nasal polyps are more common in adults than children and tend to recur.

Causes

Nasal polyps usually are produced by continuous pressure, resulting from a chronic allergy that causes prolonged mucous membrane edema in the nose and sinuses. Other predisposing factors include chronic sinusitis, chronic rhinitis, recurrent nasal infections, cystic fibrosis, disorders of ciliary motility, and extrinsic stimuli such as smoke.

Complications

Nasal polyps may result in airway obstruction.

Assessment findings

Patient history may detail chronic allergic rhinitis, chronic sinusitis, and recurrent nasal infections. The patient may describe nasal obstruction, mouth breathing, sneezing, excessive tearing, watery mucus discharge, loss of smell, a sensation of fullness in the face, a nasal discharge, and shortness of breath.

Inspection of the intranasal area discloses a dry, red surface, with pale, clear, or gray soft growths. Large growths may resemble tumors. In contrast to normal nasal tissue, probing or manipulation doesn't elicit pain when these growths are present.

Diagnostic tests

X-rays of the sinuses and nasal passages reveal soft tissue shadows over the affected areas. Nasal polyps in children require further testing to rule out cystic fibrosis. Immunologic assessment and testing may be considered if allergy is the causative factor. A computed tomography scan may be done to evaluate bone and sinuses.

Treatment

Treatment usually consists of corticosteroids (either by direct injection into the polyps or by local spray) to temporarily reduce the polyp. Treatment of the underlying cause may include antihistamines to control allergy and antibiotic therapy if infection is present. Local application of an astringent shrinks hypertrophied tissue.

Systemic steroids are used with caution in a severely obstructed airway; they may be injected into the polyps. Steroid nasal sprays may be used to reduce inflammation and reduce the polyps' size. Such therapies alone are rarely effective; consequently, the treatment of choice is polypectomy (intranasal removal of the polyp with a wire snare), usually performed under local anesthesia. Continued recurrence may require surgical opening of the ethmoid and maxillary sinuses and evacuation of diseased tissue.

Caldwell-Luc surgery may be done to allow entry into the maxillary sinus for polyp removal.

Nursing diagnoses

- u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for infection u Risk for injury

Key outcomes

- u The patient will express feelings of comfort.
- u The patient won't experience injury or harm.
- u The patient will have a patent airway and breathing rate within ± 5 of normal.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will avoid complications.

Nursing interventions

- u For the patient with allergies, administer antihistamines as ordered and monitor response.
- u Insure adequate hydration and humidification.
- u Monitor the effects of nasal sprays.

After surgery:

- u Monitor for excessive bleeding or other drainage and promote the patient's comfort. Give pain medications as ordered and monitor the patient's response.
- u Elevate the head of the bed to aid breathing, promote adequate drainage, and reduce swelling. Change the mustache dressing or drip pad as needed; record the consistency, amount, and color of nasal drainage.
- u Intermittently apply ice compresses over the nostrils to reduce swelling, prevent bleeding, and relieve pain.
- u If nasal bleeding occurs—most likely after packing is removed—elevate the head of the bed, monitor vital signs, and advise the patient not to swallow blood. Compress the outside of the nose against the septum for 10 to 15 seconds. If bleeding persists, notify the doctor immediately; nasal packing may be necessary.

Patient teaching

- u Prepare the patient for surgery by explaining what to expect postoperatively such as nasal packing for 1 to 2 days.
- u To prevent recurrence of polyps, instruct the patient with allergies to avoid exposure to allergens and to take antihistamines at the first sign of an allergic reaction. Teach him to identify potential triggers to allergic reactions and to avoid them if possible.
- u Advise the patient to avoid overuse of nose drops and sprays. Teach the proper use of nasal sprays.

- u Teach the patient about medications prescribed, as well as adverse effects, dosage, and administration.
- u Caution the patient to report any adverse effects to prescribed medications.
- u Instruct the patient to avoid situations, such as crowds, that may predispose the patient to illness.

SEPTAL PERFORATION AND DEVIATION

Septal perforation, a hole in the nasal septum between the two air passages, usually occurs in the anterior cartilaginous septum but may also occur in the bony septum. Septal deviation is a shift from the midline, which is common in adults, and may be severe enough to obstruct the passage of air through the nostrils. With surgical correction, the prognosis for either disorder is good.

Causes

Septal perforation can result from several factors, including a traumatic irritation, excessive nose picking, perichondritis, syphilis, tuberculosis, untreated septal hematoma, inhalation of irritating chemicals, cocaine snorting, congenital disproportion, chronic nasal infections, nasal carcinoma, granuloma, and chronic sinusitis. Less frequently, it results from repeated cauterization for epistaxis.

Septal deviation may develop during growth as the septum shifts from one side to the other. It also can result from nasal trauma due to a fall, a blow to the nose, or surgery that further exaggerates the deviation. Congenital deviation is rare.

Complications

Hemorrhage, infections, and deformity are possible complications of both septal perforation and deviation. Other complications include nasal obstruction, epistaxis, osmotic nasal deformity, and sinusitis.

Assessment findings

Although a small septal perforation usually produces no symptoms, the patient may complain of hearing a whistling noise on inspiration. A patient with a large perforation may report a history of rhinitis and epistaxis. The patient's history also may reveal a possible cause of the perforation, such as chronic sinusitis, tuberculosis, or inhalation of irritating chemicals. Inspection may reveal nasal crusting and a watery discharge. Inspection with a nasal speculum may also reveal the septal perforation.

The patient with a deviated septum may report a recent traumatic injury to the nose or a history of nasal obstruction. He may complain of a sensation of fullness in the face; shortness of breath; difficulty breathing through the nose; edema in the nasal mucosa; dry, cracked, or crusted nasal mucosa; swelling of the face and ecchymosis from recent trauma; nasal discharge; recurring epistaxis; infection; sinusitis; and headache. Inspection may disclose a crooked nose as the midline deflects to one side.

Diagnostic tests

No specific diagnostic tests exist. However, clinical inspection confirms septal perforation or deviation and X-rays of the skull reveal nasal and skull fractures.

Treatment

Based on the patient's symptoms, treatment for a perforated septum may include decongestants to reduce nasal congestion by local vasoconstriction, nasal steroid sprays to decrease edema, local application of lanolin or petroleum jelly to prevent ulceration and crusting, and antibiotics to combat infection. Surgery may be necessary to graft part of the perichondrial layer over the perforation. Also, a plastic or Silastic "button" prosthesis may be used to close the perforation.

Treatment of a deviated septum is also based on the patient's symptoms. It usually includes analgesics to relieve headache, decongestants to minimize secretions, and vasoconstrictors, nasal packing, or cauterization as needed to control hemorrhage. Manipulation of the nasal septum at birth can correct congenital deviated septum.

Corrective surgery may consist of reconstruction of the nasal septum by submucous membrane resection to reposition the nasal septal cartilage and relieve nasal obstruction. Other surgical procedures include rhinoplasty to correct nasal structure deformity by intranasal incisions and septoplasty to relieve nasal obstruction and enhance cosmetic appearance. Surgical complications include possible hemorrhage, infection, and deformity.

Nursing diagnoses

u Altered oral mucous membrane u Anxiety u Ineffective airway clearance u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for fluid volume deficit u Risk for infection

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will maintain a patent airway and acceptable breathing pattern.
- u The patient and family members will express an understanding of the disorder and treatment.
- u The patient won't develop complications.

Nursing interventions

- u Answer the patient's questions, and encourage him to express his concerns. Include the patient and family members in care decisions.
- u For the patient with a perforated septum, use a cotton applicator to apply petroleum jelly to the nasal mucosa to minimize crusting and ulceration.
- u To relieve nasal congestion, instill normal saline solution and provide a humidifier. Give decongestants and nasal sprays as ordered.
- u If the patient experiences epistaxis, elevate the head of the bed, provide an emesis basin, and instruct the patient to expectorate any blood. Compress the outer nose portion against the septum for 10 to 15 minutes and apply ice packs. If bleeding persists, notify the doctor.

After surgery:

- u To prevent or reduce edema and promote drainage, place the patient in semi-Fowler's position and use a cool-mist vaporizer to liquefy secretions and facilitate normal breathing. To reduce facial edema and pain, place crushed ice in a rubber glove or a small ice bag and apply over the eyes and nose intermittently for 24 hours.
- u Because the patient is breathing through the mouth, provide frequent and meticulous mouth care.
- u Change the mustache dressing or drip pad as needed. Record the color, consistency, and amount of drainage. While nasal packing is in place, expect slight, bright-red drainage, with clots. After the packing is removed, watch for purulent discharge, an indication of infection.
- u Watch for and report excessive swallowing, hematoma, or a falling or flapping septum (depressed or soft and unstable septum). Perform an intranasal examination to detect hematoma formation. Because these complications require surgical correction, notify the doctor immediately.
- u Administer sedatives and analgesics as ordered and monitor the patient's response to these medications.

Patient teaching

- u If corrective surgery is scheduled, prepare the patient to expect postoperative facial edema, periorbital bruising, and nasal packing, which wont remain in place for 12 to 24 hours and force the patient to breathe through the mouth. Tell the patient that a splint may be placed on the nose after surgery. Instruct him to remain in an upright position after surgery to aid in breathing and minimize nasal edema.
- u Explain the anticoagulant properties of aspirin, products containing aspirin and its derivatives, and alcohol and advise the patient to avoid these items. Review the purpose of medications, their correct administration, and possible adverse effects.
- u Warn the patient with perforation or severe deviation against nose blowing, even after nasal packing is removed, because it may cause bruising, bleeding, and swelling. After surgery, advise the patient to limit physical activity for 2 or 3 days. If he smokes, advise him to stop smoking for at least 2 days.
- u Explain to the patient that his sense of smell may be decreased and that he may feel anorexic for a while after surgery.

SINUSITIS

Inflammation of the paranasal sinuses may be acute, subacute, chronic, allergic, or hyperplastic. Acute sinusitis usually results from the common cold; in about 10% of patients, it lingers in subacute form. Chronic sinusitis follows persistent bacterial infection, generally occurring when a cold spreads to the sinuses.

Allergic sinusitis accompanies allergic rhinitis. Hyperplastic sinusitis is a combination of purulent acute sinusitis and allergic sinusitis or rhinitis. For all types, the prognosis is good.

Causes

Sinusitis usually results from a bacterial infection (*Haemophilus influenzae*, anaerobes) or, less frequently, from a viral infection. Viral sinusitis usually follows an upper respiratory infection in which the virus penetrates the normal mucous membrane, decreasing ciliary transport.

Fungal sinusitis is uncommon and found more often in immunosuppressed patients. The most common types are aspergillosis, mucomycosis, candidiasis, histoplasmosis, and coccidiomycosis. The spores causing them are usually found in soil and enter through the respiratory tract.

Acute sinusitis is most commonly caused by *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *S. pyogenes*. Predisposing factors include any condition that interferes with sinus drainage and ventilation, such as chronic nasal edema, a deviated septum, and viscous mucus. Bacterial invasion also may result from swimming in contaminated water. Generalized debilitating conditions, including chemotherapy, malnutrition, diabetes, blood dyscrasias, long-term steroids, and immunodeficiency, may also predispose an individual to sinusitis.

Understanding brain abscess

Brain (intracranial) abscess is free or encapsulated purulence, typically in the frontal, parietal, temporal, or occipital lobes or, less commonly, in the cerebellum or basal ganglia. It can occur at any age (mostly between ages 10 and 35) and is rare in elderly people.

Brain abscess is usually secondary to another infection, most commonly mastoid or ear infection. Untreated brain abscess is usually fatal; with treatment, the prognosis is only fair.

Typically, the patient reports recent or recurrent infection or a history of congenital heart disease. Nausea, vomiting, and a constant, intractable headache may occur along with changes in level of consciousness, confusion or disorientation, and signs of a focal neurologic disorder. Signs of increased intracranial pressure (ICP) may be seen, including abnormal pupillary response and depressed respirations.

EEG, computed tomography scanning and, occasionally, arteriography identify the abscess site. Cerebrospinal fluid analysis can help to confirm infection but is risky because the process can provoke cerebral herniation. Other tests include culture and sensitivity tests, skull X-rays, and radioisotope scans.

Therapy consists of antibiotics and surgical aspiration, drainage, or removal of the abscess (after it becomes encapsulated). Other treatments may include mechanical ventilation, I.V. fluid and diuretic administration, and glucocorticoids to combat increased ICP and cerebral edema. Anticonvulsants help prevent seizures.

Complications

Complications—typically resulting from inadequate therapy during the acute phase or from a delay in treatment—may include meningitis, cavernous and sinus thrombosis, bacteremia or septicemia, brain abscess, frontal lobe abscess, osteomyelitis, mucocele, and orbital cellulitis or abscess. (See [Understanding brain abscess.](#))

Locating the paranasal sinuses

The location of a patient's sinusitis pain indicates the affected sinus. For example, an infected maxillary sinus can cause tooth pain. (Note: The sphenoid sinus, which lies under the eye and above the soft palate, isn't depicted here.)

Assessment findings

A patient with acute sinusitis typically complains of nasal congestion that preceded a gradual buildup of pressure in the affected sinus. He may state that for 24 to 48 hours after onset, a nasal discharge was present and later became purulent. He may also list a sore throat, a localized headache, and a general feeling of malaise.

The patient may point to pain specific to the affected sinus: in the cheeks and upper teeth (maxillary sinusitis); over the eyes (ethmoid sinusitis); over the eyebrows

(frontal sinusitis); or behind the eyes, over the occiput, or at the top of the head (sphenoid sinusitis, a rare condition).

The patient also may report purulent nasal drainage that continues longer than 3 weeks after an acute infection subsides, which usually suggests subacute sinusitis. The patient with chronic sinusitis may report continuous and mucopurulent discharge. In the acute form, the patient may complain of a stuffy nose, vague facial discomfort, edema, edematous nasal mucosa, fatigue, and a nonproductive cough.

Assessment of vital signs may reveal a low-grade fever of 99° to 99.5° F (37.2° to 37.5° C).

The areas over the sinuses may appear swollen (caused by bacterial growth on diseased tissue in hyperplastic sinusitis). Inspection also may reveal enlarged turbinates and thickening of the mucosal lining and mucosal polyps (hyperplastic sinusitis). Palpation may cause pain and pressure over the affected sinus areas. Transillumination may expose diminished areas of light, which indicate areas of purulent drainage that prevent the passage of light. (See [Locating the paranasal sinuses.](#))

Diagnostic tests

Sinus X-rays reveal cloudiness in the affected sinus, air-fluid levels, or a thickened mucosal lining; ultrasonography and computed tomography scanning may uncover suspected complications, recurrent or chronic sinusitis, or unresolved and serious sinusitis.

Antral puncture promotes drainage and removal of purulent material. It also may be used to collect a specimen for culture and sensitivity identification of the infecting organism, but this test is rarely performed. Sinus endoscopy indicates purulent nasal drainage, nasal edema, and obstruction of ostia.

Treatment

Antibiotics are the primary treatment for acute sinusitis. Analgesics may be prescribed to relieve pain. Other appropriate measures include vasoconstrictors, such as epinephrine and phenylephrine, to decrease nasal secretions. Steam inhalation also promotes vasoconstriction and encourages drainage.

Antibiotic therapy—usually with amoxicillin or ampicillin—combats persistent infection. Local heat applications may help to relieve pain and congestion.

In subacute sinusitis, antibiotic therapy also is the primary treatment. As in acute sinusitis, vasoconstrictors may reduce nasal secretions.

Severe allergic symptoms may require treatment with corticosteroids and epinephrine.

In both chronic sinusitis and hyperplastic sinusitis, antibiotics and a steroid nasal spray may relieve pain and congestion. Antihistamines may be judiciously prescribed for symptom relief but are administered cautiously because they may thicken nasal secretions and prevent effective sinus drainage.

If a subacute infection persists, the maxillary sinus may be irrigated. The ethmoid and sphenoid sinuses can be drained indirectly with the Poetz displacement method—a technique that uses gravity to displace thick, purulent material with thin irrigating fluid. If these irrigating techniques fail to relieve symptoms, one or more sinuses may require surgery. (See [Surgery for chronic and hyperplastic sinusitis.](#))

Nursing diagnoses

u Altered oral mucous membrane u Anxiety u Fear u Ineffective airway clearance u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for infection u Sensory or perceptual alterations

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will exhibit an adequate breathing pattern.
- u The patient will remain free from signs and symptoms of infection.
- u The patient will express an understanding of the condition and treatment.
- u The patient won't develop complications.

Nursing interventions

- u Enforce bed rest and encourage the patient to drink plenty of fluids to promote drainage. Don't elevate the head of the bed more than 130 degrees.
- u Encourage the patient to express his concerns, and answer his questions. Include the patient and family members in planning and implementing the patient's care.
- u To relieve pain and promote drainage, apply warm compresses continuously or four times daily at 2-hour intervals. Administer analgesics, vasoconstrictors, nasal sprays, antibiotics, antifungals, and antihistamines as ordered and as needed, monitoring the patient's response. Humidifiers and saline dressings are also helpful.
- u Watch for and report vomiting, chills, fever, edema of the forehead or eyelids, blurred or double vision, and personality changes, which could indicate complications.

After surgery:

- u Monitor for excessive drainage or bleeding.
- u To prevent edema and promote drainage, place the patient in semi-Fowler's position. To relieve edema and pain and minimize bleeding, apply ice compresses or a rubber glove filled with ice chips over the nose and iced saline gauze over the eyes. Continue these measures for 24 hours.
- u Frequently change the mustache dressing or drip pad, recording the consistency, amount, and color of drainage (expect scant, bright-red drainage with some clots).
- u Because the patient is breathing through the mouth, provide meticulous and frequent mouth care.

ADVANCED PRACTICE

Surgery for chronic and hyperplastic sinusitis

When drug therapy and irrigation fail to relieve infection, surgery may be necessary to correct chronic and hyperplastic sinusitis. The following procedures are common.

For maxillary sinusitis

- *Nasal window procedure* creates an opening in the sinus, allowing secretions and pus to drain through the nose.
- *Caldwell-Luc procedure* removes diseased mucosa in the maxillary sinus through an incision under the upper lip.

For chronic ethmoid sinusitis

- *Ethmoidectomy* removes all infected tissue through an external or intranasal incision into the ethmoid sinus.
- *External ethmoidectomy* removes infected ethmoid sinus tissue through a crescent-shaped incision, beginning under the inner eyebrow and extending along the side of the nose.

For chronic frontal sinusitis

- *Fronto-ethmoidectomy* removes infected frontal sinus tissue through an extended external ethmoidectomy.
- *Osteoplastic flap* drains the sinuses through an incision across the skull, behind the hairline.

Patient teaching

- Inform the patient about prescribed medications, including action, dosage, and adverse effects. For antihistamines or analgesics, including narcotics, caution against driving a motor vehicle or consuming alcohol. Tell the patient to complete the full course of therapy for prescribed antibiotics even if symptoms disappear.
- If surgery is necessary, tell the patient that nasal packing is left in place for 12 to 24 hours following surgery. The patient needs to breathe through the mouth; to refrain from nose blowing, which may cause bleeding and swelling; and to try not to sneeze.
- If the patient is a smoker, instruct him to refrain for at least 2 to 3 days after surgery.
- Inform the patient undergoing a Caldwell-Luc procedure that the operative area may be numb for several weeks. Advise him against wearing dentures for several weeks or nose blowing for 2 weeks following packing removal.
- Reinforce the patient's understanding of sinusitis, review signs and symptoms of complications, and emphasize the importance of medical follow-up.
- Discuss proper disposal of tissues and review hand-washing technique to prevent the spread of infection.
- Teach the patient to avoid bending and stooping during the acute phase of sinusitis to avoid increased pain. Advise against contact with people known to have infections.

Throat disorders

Throat disorders—characterized by a sore throat, dysphagia, hoarseness, and airway obstruction— may be caused by bacterial, fungal, or viral infections; an aneurysm; surgical trauma; cancer; smoking; and overuse of the vocal cords. These disorders include juvenile angiofibroma, laryngitis, pharyngitis, tonsillitis, vocal cord nodules and polyps, and vocal cord paralysis.

JUVENILE ANGIOFIBROMA

Juvenile angiofibroma—an uncommon disorder—is a highly vascular, nasopharyngeal tumor made up of masses of fibrous tissue containing many thin-walled blood vessels. These tumors are found primarily in adolescent males and are extremely rare in females. Incidence is higher in Egypt, India, Southeast Asia, and Kenya than in the United States and Europe. The prognosis is good with treatment.

Causes

Although its cause is unknown, juvenile angiofibroma has been identified as a type of hemangioma and can be classified as benign or malignant.

Complications

Juvenile angiofibroma may result in secondary anemia due to tumor bleeding or cerebrospinal fluid leak.

Assessment findings

Usually between ages 7 and 21, the patient reports a history of unilateral or bilateral nasal obstruction and severe recurrent epistaxis. The patient also may reveal a history of purulent rhinorrhea and serous otitis media, with resultant hearing loss from eustachian tube obstruction. Inspection may reveal facial deformity and nasal speech.

Diagnostic tests

Examination with a nasopharyngeal mirror or nasal speculum permits visualization of the tumor, which appears as a blue mass in the nose or nasopharynx, and X-rays show bowing of the posterior wall of the maxillary sinus.

Angiography is used to determine the size and location of the tumor and source of vascularization. A computed tomography scan allows visualization of vascular mass.

Biopsy is contraindicated because of the danger of hemorrhage.

Treatment

Several surgical methods, ranging from avulsion to cryosurgical techniques, are used to treat juvenile angiofibroma. Whichever surgical method is used, the tumor must be removed in its entirety and not in pieces. Embolization with a substance to occlude the vessels may decrease the potential for bleeding. Excision is usually rescheduled 12 days after embolization to allow inflammation to decrease. Surgical excision is preferred after embolization with Teflon or an absorbable gelatin sponge to decrease vascularization. Blood transfusions may be necessary during avulsion. Preoperative hormonal therapy may decrease the tumor's size and vascularity.

Although radiation therapy produces only a temporary regression in an angiofibroma, it remains the treatment of choice if the tumor has expanded into the cranium or ocular orbit. Because the tumor is multilobular and locally invasive, recurrent symptoms are common (occurring in about 30% of patients) during the first year after treatment but are uncommon after 2 years.

Nursing diagnoses

- Altered oral mucous membrane
- Altered skin integrity
- Altered tissue perfusion (peripheral)
- Anxiety
- Fear
- Knowledge deficit
- Pain
- Risk for infection
- Risk for injury
- Sensory or perceptual alterations

Key outcomes

- u The patient will demonstrate adequate tissue perfusion.
- u The patient and family members will express their concerns about the condition.
- u The patient won't experience injury or harm.
- u The patient's oral mucous membranes will be intact.
- u The patient and family members will express an understanding of the condition and treatment.

Nursing interventions

- u If the patient has experienced hearing loss, provide a means to facilitate communication. Face the patient when speaking; speak in a slow, calm voice; and alert other staff to his communication problem. Develop alternate means of communication, such as a small chalkboard, a slate, or a pad and pencil.
- u Answer questions and encourage the patient and family members to discuss their concerns. Include the patient and family members in all phases of care.
- u Provide humidification.

After surgery:

- u Report excessive bleeding immediately. Check hemoglobin levels and hematocrit for anemia. Make sure an adequate supply of typed and cross-matched blood is available for transfusion.
- u Monitor for any change in vital signs.
- u Provide meticulous and frequent mouth care and use a bedside vaporizer to increase humidity.
- u During blood transfusion, watch for transfusion reactions, such as fever, chills, or a rash. If any of these reactions occur, discontinue the transfusion and notify the doctor immediately.

Patient teaching

- u Explain all diagnostic and surgical procedures. Provide emotional support because severe epistaxis frightens many patients and family members to the point of panic.
- u Instruct the patient and family members to seek immediate medical attention if bleeding occurs after discharge and teach them how to apply pressure over the affected area.
- u Stress the importance of providing adequate humidification at home to keep nasal mucosa moist.
- u Instruct the patient to avoid crowds and people with respiratory infections.

LARYNGITIS

Laryngitis—a common disorder—is an acute or chronic inflammation of the vocal cords. Acute laryngitis may occur as an isolated infection or as part of a generalized bacterial or viral upper respiratory tract infection. Repeated attacks of acute laryngitis cause inflammatory changes associated with chronic laryngitis.

Causes

Acute laryngitis usually results from infection or excessive use of the voice, an occupational hazard in certain vocations (for example, teaching, public speaking, and singing). It also may result from overuse of the voice, such as cheering at a sports event; inhalation of smoke or fumes; or aspiration of caustic chemicals. Causes of chronic laryngitis include chronic upper respiratory tract disorders (sinusitis, bronchitis, nasal polyps, allergy), mouth breathing, smoking, constant exposure to dust or other irritants, alcohol abuse, and gastroesophageal reflux or reflux esophagitis.

Complications

Chronic laryngitis may result in permanent laryngeal tissue changes accompanied by hoarseness. Severe, acute laryngitis occasionally results in airway obstruction.

Assessment findings

In acute laryngitis, the patient typically complains of hoarseness, ranging from mild to complete loss of voice. The patient also may report pain (especially when swallowing or speaking), a dry cough, and malaise.

In chronic laryngitis, hoarseness may be the patient's only complaint. Obtain a detailed patient history to help determine the disorder's cause.

Diagnostic tests

Indirect laryngoscopy is used to confirm the diagnosis by revealing red, inflamed and, occasionally, hemorrhagic vocal cords with rounded rather than sharp edges and with exudate. Bilateral swelling that restricts movement but doesn't cause paralysis also may be apparent.

Treatment

Resting the voice is the primary treatment. For viral infection, care is based on the patient's symptoms and includes analgesics and throat lozenges for pain relief. In addition, humidification, resting the voice, avoidance of smoking, elevating the head of the bed, drinking cold fluids, and advising the patient not to whisper is helpful. Bacterial infection requires antibiotic therapy. Severe, acute laryngitis may necessitate hospitalization. Occasionally, when laryngeal edema results in airway obstruction, a tracheotomy may be necessary. In chronic laryngitis, effective treatment must eliminate the underlying cause.

Nursing diagnoses

u Anxiety u Fatigue u Fear u Impaired verbal communication u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for aspiration

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will exhibit adequate breathing patterns.
- u The patient will maintain a patent airway.
- u The patient will develop alternate means of communication.

Nursing interventions

- u Encourage the patient to discuss his concerns about impaired communication. Answer his questions as best as you can.
- u In severe, acute laryngitis, monitor the patient for signs and symptoms of airway obstruction (tachycardia, use of accessory muscles, anxiety, and stridor). Keep a tracheotomy tray at the bedside.
- u If the patient has chronic laryngitis, encourage modification of habits that predispose him to the disorder.
- u Place a sign over the bed to remind others of the patient's restrictions on verbal communication. Provide a small chalkboard, slate, pad and pencil, or alphabet board for communication. Mark the intercom panel so that other staff members are aware that the patient can't answer. Minimize the patient's urge to talk by trying to anticipate his needs.

- u Provide analgesics as needed and monitor the patient's response.

Patient teaching

- u Explain to the patient why he shouldn't talk, and teach alternate methods of communication such as flash cards. If he must talk, tell him to speak softly rather than whisper.
- u Suggest that the patient maintain adequate humidification by using a vaporizer or humidifier during the winter, by avoiding air conditioning during the summer (because it dehumidifies), by using medicated throat lozenges, and by not smoking.
- u Teach the patient to avoid crowds, strenuous activity, and smoky environments to minimize edema and discomfort.
- u Review medications with the patient and instruct him to finish prescribed antibiotics. Tell the patient to report any adverse effects.

PHARYNGITIS

Pharyngitis, the most common throat disorder, is an acute or chronic inflammation of the pharynx. It's widespread among adults who live or work in dusty or dry environments, use their voices excessively, habitually use tobacco or alcohol, or suffer from chronic sinusitis, persistent coughs, or allergies. Uncomplicated pharyngitis usually subsides in 3 to 10 days.

Beta-hemolytic streptococci, which account for 15% to 20% of acute pharyngitis, may precede the common cold or other communicable diseases. Chronic pharyngitis commonly is an extension of nasopharyngeal obstruction or inflammation.

Viral pharyngitis accounts for approximately 70% of acute pharyngitis cases.

Causes

Pharyngitis may occur as a result of a virus such as the Epstein-Barr virus. Mononucleosis can cause pharyngitis. In children, streptococcal bacteria often cause pharyngitis. Fungal pharyngitis can develop with prolonged use of antibiotics in an immunosuppressed patient, such as a patient with human immunodeficiency virus. Gonococcal pharyngitis is caused by release of a toxin produced by *Corynebacterium diphtheriae*.

Complications

If pharyngitis is caused by a bacterial infection, complications may include otitis media, sinusitis, mastoiditis, rheumatic fever, and nephritis.

Assessment findings

Typically, the patient complains of a sore throat and slight difficulty swallowing; swallowing saliva hurts more than swallowing food. The patient also may complain of a sensation of a lump in the throat, a constant and aggravating urge to swallow, a headache, and muscle and joint pain (especially in bacterial pharyngitis). Assessment of vital signs may reveal mild fever.

On inspection, the posterior pharyngeal wall appears fiery red, with swollen, exudate-flecked tonsils and lymphoid follicles. If the patient has bacterial pharyngitis, the throat is acutely inflamed, with patches of white and yellow follicles. The tongue may be strawberry red in color.

Neck palpation may reveal enlarged, tender cervical lymph nodes.

Diagnostic tests

Throat culture may be used to identify the bacterial organisms causing the inflammation but it may not detect other causative organisms. Rapid strep tests generally detect group A streptococcal infections, but they miss the fairly common streptococcal groups C and G.

Computed tomography scanning is helpful in identifying location of abscesses.

A white blood cell (WBC) count is used to determine atypical lymphocytes; an elevated total WBC count is present.

Treatment

Based on the patient's symptoms, treatment for acute viral pharyngitis consists mainly of rest, warm saline gargles, throat lozenges containing a mild anesthetic, plenty of fluids, and analgesics as needed. If the patient can't swallow fluids, he may need hospitalization for I.V. hydration.

Bacterial pharyngitis requires rigorous treatment with penicillin (or another broad-spectrum antibiotic if the patient is allergic to penicillin) because streptococcus is the chief infecting organism. Antibiotic therapy should continue for 48 hours after visible signs of infection have disappeared or for at least 7 to 10 days. Antifungal agents are used to treat fungal pharyngitis. Equine antitoxins are given for diphtheria pharyngitis.

Chronic pharyngitis necessitates the same supportive measures as acute pharyngitis but with greater emphasis on eliminating the underlying cause such as an allergen.

Preventive measures include adequate humidification and avoiding excessive exposure to air conditioning. In addition, patients who smoke should be urged to stop.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered oral mucous membrane
- u Fatigue
- u Knowledge deficit
- u Pain
- u Risk for fluid volume deficit

Key outcomes

- u The patient will express feelings of comfort.
- u The patient will consume adequate daily calorie intake.
- u The patient's mucous membranes will remain intact.
- u The patient's fluid volume will remain within normal range.

Nursing interventions

- u Administer analgesics and warm saline gargles as ordered and as appropriate.
- u Encourage the patient to drink plenty of fluids (up to 2.5 L [2.6 qt] per day). Monitor intake and output scrupulously, and watch for signs of dehydration (cracked lips, dry mucous membranes, low urine output, poor skin turgor). Provide meticulous mouth care to prevent dry lips and oral pyoderma and maintain a restful environment.
- u Obtain throat cultures and administer antibiotics as ordered.
- u Maintain the patient on bed rest, especially while febrile, to conserve energy.
- u Encourage a soft, light diet with plenty of liquids to combat the commonly experienced anorexia. Antiemetics can be given before eating if ordered.
- u Examine the skin twice a day for possible drug sensitivity rashes or for rashes indicating a communicable disease.
- u Administer antitussives as ordered if the patient has a cough.
- u Administer analgesics as ordered.

Patient teaching

- u If the patient has acute bacterial pharyngitis, emphasize the importance of completing the full course of antibiotic therapy. Tell him to call the doctor if any adverse effects develop.
- u Advise the patient with chronic pharyngitis how to minimize sources of throat irritation in the environment such as using a bedside humidifier. Refer him to a self-help group to stop smoking if appropriate.
- u Inform the patient and family members that in the case of a positive streptococcal infection, all family members should undergo throat cultures regardless of the presence or absence of symptoms. Individuals with positive cultures require penicillin therapy.
- u Teach the patient to avoid using irritating agents, such as alcohol, which may exacerbate symptoms.

Understanding throat abscesses
<p>Throat abscesses may be peritonsillar or retropharyngeal. Peritonsillar abscess, usually unilateral, is most common in adolescents and young adults. Acute retropharyngeal abscess commonly affects children under age 2. Chronic retropharyngeal abscess can occur at any age.</p> <p>Peritonsillar abscess follows acute tonsillitis, usually from streptococcal or staphylococcal infection. Acute retropharyngeal abscess commonly follows upper respiratory tract infection. Chronic retropharyngeal abscess results from tuberculosis of the cervical spine.</p> <p>Peritonsillar abscess causes severe throat pain and, possibly, ear pain, gland tenderness, swallowing difficulty, chills and fever, malaise, rancid breath, nausea and, sometimes, spasm of the jaw muscles and muffled speech. Retropharyngeal abscess may cause pain, dysphagia, fever, nasal or laryngeal obstruction, neck hyperextension and, in children, drooling and muffled crying. The soft palate and posterior pharyngeal wall may be red and swollen, displacing the tonsils or uvula.</p> <p>X-rays may show a displaced larynx. Throat culture and sensitivity testing isolates the causative organism. A computed tomography scan can enable viewing of abscesses.</p> <p>Early peritonsillar abscess necessitates large doses of antibiotics. Late-stage abscess with cellulitis usually requires incision and drainage, followed by I.V. antibiotic therapy. Chronic recurrence may necessitate tonsillectomy. Retropharyngeal abscess may require drainage by incision or needle aspiration, followed by analgesics and I.V. antibiotics.</p>

TONSILLITIS

Inflammation of the tonsils can be acute or chronic. The uncomplicated acute form usually lasts 4 to 6 days and commonly affects children between ages 5 and 10. Tonsils tend to hypertrophy during childhood and atrophy after puberty.

Causes

Tonsillitis generally results from infection with beta-hemolytic streptococci but can also result from other bacteria or viruses.

Complications

Chronic tonsillitis may result in chronic upper airway obstruction, causing sleep apnea or sleep disturbances, cor pulmonale, failure to thrive, eating or swallowing disorders, and speech abnormalities. Febrile seizures, otitis media, cardiac valvular disease, abscesses, glomerulonephritis, subacute bacterial endocarditis, and abscessed cervical lymph nodes also may occur. (See [Understanding throat abscesses.](#))

Assessment findings

The patient with acute tonsillitis may complain of mild to severe sore throat. In a child too young to complain about throat pain, the parents may report that the child has stopped eating. The patient or his parents also may report muscle and joint pain, chills, malaise, headache, and pain that is frequently referred to the ears. Because of excess secretions, the patient may complain of a constant urge to swallow and a constricted feeling in the back of the throat. Such discomfort usually subsides after 72 hours.

Fever may be present, and palpation may reveal swollen, tender lymph nodes in the submandibular area.

Inspection of the throat may discover generalized inflammation of the pharyngeal wall, with swollen tonsils that project from between the pillars of the fauces and exude white or yellow follicles. Purulent drainage becomes apparent when you apply pressure to the tonsillar pillars. The uvula may also be edematous and inflamed.

In chronic tonsillitis, the patient may report recurrent sore throats and attacks of acute tonsillitis. Inspection may expose purulent drainage in the tonsillar crypts.

Diagnostic tests

Throat culture may reveal the infecting organism and indicate appropriate antibiotic therapy. A white blood cell count usually reveals leukocytosis.

Treatment

Management of acute tonsillitis stresses symptom relief and requires rest, adequate fluid intake, aspirin or acetaminophen and, for bacterial infection, antibiotics. For group A beta-hemolytic streptococcus, penicillin is the drug of choice. (Erythromycin or another broad-spectrum antibiotic may be given if the patient is allergic to penicillin.) To prevent complications, antibiotic therapy should continue for 10 days.

Chronic tonsillitis or complications may require tonsillectomy but only after the patient has been free of tonsillar or respiratory tract infections for 3 to 4 weeks.

Nursing diagnoses

- u Anxiety u Ineffective breathing pattern u Knowledge deficit u Pain u Risk for aspiration u Risk for fluid volume deficit

Key outcomes

- u The patient will express feelings of comfort.
- u The patient won't show signs of aspiration.
- u The patient's breathing pattern will remain within ±5 of baseline.
- u The patient will have adequate fluid volume, with intake equal to output.

Nursing interventions

- u Despite dysphagia, urge the patient to drink plenty of fluids, especially if fever is present. Offer a child ice cream and flavored drinks and ices. Assess hydration status. Increased humidification may provide comfort.

- u Monitor the effect of pain medication.
- u Suggest gargling to soothe the throat.
- u Before surgery, assess for bleeding abnormalities.

After surgery:

- u Maintain a patent airway. To prevent aspiration, place the patient on his side. Keep suction equipment nearby.
- u Monitor vital signs frequently and check for bleeding. Immediately report excessive bleeding, increased pulse rate, or decreasing blood pressure.
- u When the patient is fully alert and the gag reflex has returned, give him water. Later, encourage him to drink nonirritating fluids. Avoid milk products; they coat the throat, causing throat clearing and increasing the risk of bleeding.
- u Provide analgesics for pain relief. Because crying irritates the operative site, keep the child comfortable.
- u Encourage deep-breathing exercises to prevent pulmonary complications.

Patient teaching

- u Tell the patient to complete the entire course of antibiotics.
- u Instruct the patient to avoid smoking and drinking alcohol because they cause irritation.
- u Review the patient's medications, dosage administration, and possible adverse effects.
- u Before surgery, explain tonsillectomy to the pediatric patient in a simple, nonthreatening way. Show him the operating and recovery rooms and briefly explain the facility routine. Note if a parent may stay with him.

HOME CARE

Promoting recovery from tonsillitis

For a patient recovering from tonsillitis, provide these guidelines:

- u Make sure the patient or his parents understand the importance of completing the prescribed course of antibiotics.
- u Explain adverse effects of the prescribed medications, especially those that demand medical attention.
- u Instruct the patient or his parents to avoid spicy, irritating foods; to eat primarily soft, nutritious foods; and to avoid using straws or forks.
- u Advise the patient or his parents to restrict activities for 7 to 10 days postoperatively and to avoid aspirin or aspirin-containing products during that time.

- u Explain to the adult patient that a local anesthetic prevents pain but allows a sensation of pressure during surgery. Warn the patient to expect considerable throat discomfort and some bleeding postoperatively.
- u Before discharge, provide written home care instructions. Tell family members to expect a white scab to form in the throat 5 to 10 days postoperatively and to report bleeding, ear discomfort, or a fever for 3 days or more. (See [Promoting recovery from tonsillitis.](#))

VOCAL CORD NODULES AND POLYPS

Teachers, singers, sports fans, and energetic children who continuously shout while playing are prone to vocal cord nodules and polyps. Vocal cord nodules, resulting from hypertrophy of fibrous tissue, form at the point where the cords come together forcibly. (See [How nodules cause hoarseness.](#))

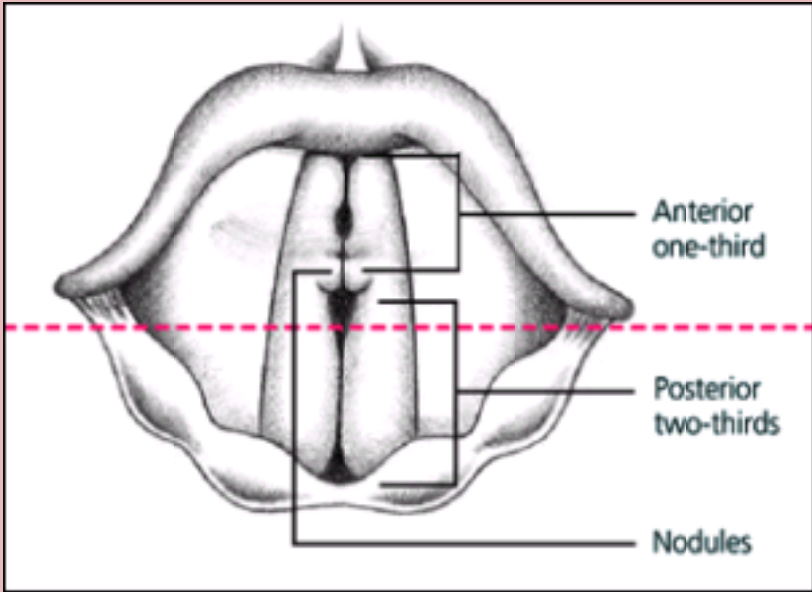

Nodules tend to be benign growths that resemble calluses on the vocal cords. Vocal cord polyps are chronic, subepithelial, edematous masses that also are common in adults who smoke, live in dry climates, or have allergies. Both nodules and polyps have good prognoses unless continued voice abuse causes recurrence with subsequent scarring and permanent hoarseness.

PATHOPHYSIOLOGY

How nodules cause hoarseness

Nodules that erupt on the vocal cords prevent the cords from closing properly (approximating) during phonation. The result is hoarseness. The most common site of vocal cord nodules is the point of maximal vibration and impact (the junction of the anterior one-third and the posterior two-thirds of the vocal cord), as depicted below.

Causes

Vocal cord nodules and polyps usually result from voice abuse, sinusitis, upper respiratory tract infections, heavy smoking, and allergies.

Complications

Permanent hoarseness is the primary complication of vocal cord nodules and polyps. Airway distress and aspiration pneumonia can also occur.

Assessment findings

The patient may report painless hoarseness and may display a breathy or husky voice. Assess for factors that might have contributed to dysphonia.

Diagnostic tests

Indirect (mirror) or direct laryngoscopy enables visualization of nodules and shows small, red nodes that eventually become white, solid nodes on one or both cords. In the patient with polyps, laryngoscopy reveals unilateral or, occasionally, bilateral sessile or pedunculated polyps of varying sizes anywhere on the vocal cords.

Treatment

Conservative management of small vocal cord nodules and polyps includes humidification, speech therapy (voice rest and training to reduce the intensity and duration of voice production), and treatment of any underlying allergies. Histamine ₂ inhibitors may be used to treat gastroesophageal reflux, antibiotics for infection, steroids to reduce swelling, and botulism injection to paralyze spastic movement.

When conservative treatment fails to relieve hoarseness, nodules or polyps require removal under direct laryngoscopy. Microlaryngoscopy may be performed for small lesions to avoid injuring the vocal cord surface. For bilateral nodules or polyps, excision may be performed in two stages to allow one cord to heal before surgery on the other cord. Two-stage excision prevents laryngeal web, which occurs when epithelial tissue is removed from adjacent cord surfaces and these surfaces grow together.

For children, treatment consists of speech therapy. If possible, surgery should be delayed until the child is old enough to benefit from voice training or until the child can understand the need to abstain from voice abuse.

Nursing diagnoses

⌞ Anxiety ⌞ Fear ⌞ Impaired verbal communication ⌞ Ineffective family coping: Disabling ⌞ Ineffective individual coping ⌞ Knowledge deficit ⌞ Risk for injury ⌞ Risk for infection

Key outcomes

- ⌞ The patient will express concerns about the condition.
- ⌞ The patient and family members will verbalize an understanding of the condition and treatment.
- ⌞ The patient won't experience injury or harm.
- ⌞ The patient will remain free from signs and symptoms of infection.
- ⌞ The patient will avoid complications.

Nursing interventions

- ⌞ Answer the patient's questions and encourage him to discuss his concerns. Include the patient and family members in all phases of care.
- ⌞ Encourage the patient to rest his voice, increase humidification, elevate the head of the bed, increase bed rest, use an ice collar, and drink cold fluids.

After surgery:

- ⌞ Provide the patient with an alternative means of communication, such as a chalkboard, slate, pad and pencil, or alphabet board. Place a sign over the bed to remind visitors that the patient shouldn't talk. Mark the intercom so other staff members are aware that the patient can't answer. Minimize the patient's urge to speak by trying to anticipate his needs.
- ⌞ Use a vaporizer to increase humidity and decrease throat irritation.
- ⌞ Make sure the patient receives speech therapy after healing if necessary because continued voice abuse causes recurrence of growths.
- ⌞ Instruct the patient to avoid crowds and people with respiratory infections.

Patient teaching

- ⌞ Postoperatively, stress the importance of resting the voice for 10 days to 2 weeks while the vocal cords heal. Encourage the patient who's a smoker to stop smoking entirely or at least refrain from smoking during recovery from surgery.
- ⌞ Teach the patient the relationship between voice abuse and vocal cord nodules and polyps and how to reduce contributing factors. Emphasize the importance of follow-up speech therapy.
- ⌞ Instruct the patient to avoid smoke and noxious fumes.

VOCAL CORD PARALYSIS

Vocal cord paralysis results from disease of or injury to the superior or, most often, the recurrent laryngeal nerve. It may be unilateral or bilateral; unilateral paralysis is most common.

Causes

Vocal cord paralysis commonly results from the accidental severing of the recurrent laryngeal nerve or one of its extralaryngeal branches during thyroidectomy or cardiac or thoracic surgery. Other causes include pressure from an aortic aneurysm or from an enlarged atrium (in patients with mitral stenosis), bronchial or esophageal carcinoma, hypertrophy of the thyroid gland, trauma (for example, neck injuries), and neuritis due to infections or metallic poisoning and injury or inflammation of the vagus nerve.

Vocal cord paralysis also can result from hysteria and, rarely, lesions of the central nervous system. Ten percent of vocal cord paralysis cases are idiopathic in nature with a possible viral etiology.

Complications

Respiratory failure resulting from airway obstruction is a major complication of bilateral vocal cord paralysis.

Assessment findings

Signs and symptoms of vocal cord paralysis depend on whether the paralysis is unilateral or bilateral and on the position of the cord or cords when paralyzed. A patient with unilateral paralysis, the most common form, may complain of vocal weakness and hoarseness. A patient with bilateral paralysis typically reports vocal weakness and may have incapacitating airway obstruction if the cords become paralyzed in the adducted position. Increased respirations, shortness of breath, dyspnea, decreasing oxygenation saturations, restlessness, decreased breath sounds, and difficulty speaking can occur.

Diagnostic tests

Indirect laryngoscopy shows one or both cords fixed in an adducted or partially abducted position. Bronchoscopy and esophagoscopy (fiber-optic techniques used to visualize the larynx) also may be used.

Treatment

Unilateral vocal cord paralysis is treated under direct laryngoscopy with injection of Teflon into the paralyzed cord. This procedure enlarges the cord and brings it closer to the other cord, usually strengthening the voice and protecting the airway from aspiration.

Bilateral cord paralysis can be a surgical emergency and generally requires a tracheotomy to restore a patent airway. Alternative treatments for adult patients include arytenoidectomy to open the glottis and lateral fixation of the arytenoid cartilage through an external neck incision. Lateralization of the vocal cords negates the need for a tracheostomy. Excision or fixation of the arytenoid cartilage improves airway patency but produces residual voice impairment. Many patients with bilateral cord paralysis prefer to keep a tracheostomy instead of having an arytenoidectomy; their voices generally are better with a tracheostomy alone than after corrective surgery.

Treatment for patients with hysterical aphonia may include psychotherapy and, for some patients, hypnosis.

Nursing diagnoses

u Anxiety u Fear u Impaired verbal communication u Ineffective individual coping u Ineffective breathing pattern u Knowledge deficit u Risk for aspiration

Key outcomes

- u The patient will express his feelings about the condition.
- u The patient will exhibit adequate breathing patterns.
- u The patient won't show signs of aspiration.
- u The patient will develop alternate means of communication.
- u The patient and family members will seek appropriate support to assist with coping.

Nursing interventions

- u For the patient choosing direct laryngoscopy and Teflon injection, provide humidified oxygen postoperatively and encourage the patient to remain mute for 24 hours.
- u Give the patient nothing by mouth for 3 to 4 hours to avoid aspiration.
- u Monitor the patient's respiratory status closely for airway obstruction.
- u Administer antibiotics and corticosteroids as ordered, and monitor the patient's response to these medications.
- u Answer the patient's questions and encourage him to discuss his concerns, offering reassurance when appropriate.
- u Monitor the effects of pain medication.
- u Monitor for signs of infection.
- u If the patient has difficulty understanding procedures because of impaired communication, give clear, concise explanations of treatments and procedures, and allow adequate time for him to grasp what is expected. Provide a pencil and paper to aid communication and alert the staff to the communication problem.
- u Because tracheotomy is performed under local anesthesia, the patient may be apprehensive. Provide emotional support and reassurance during the procedure and throughout hospitalization.

Patient teaching

- u Explain all procedures. If the patient is scheduled to undergo a tracheotomy, offer reassurance. If the patient chooses direct laryngoscopy and Teflon injection, inform him that these measures will improve his voice but won't restore it to normal. If the patient elects arytenoidectomy, explain that the tracheostomy remains in place until edema subsides and the airway is patent.
- u Instruct the patient to rest his voice for 5 to 7 days.
- u Refer the patient to a smoking cessation clinic if appropriate.
- u Instruct the patient to report signs of infection, voice changes, or breathing difficulty.
- u Arrange follow-up sessions with a speech therapist, and urge the patient to continue exercises recommended by the therapist.

For a tracheostomy patient:

- u Teach the patient how to suction, clean, and change the tracheostomy tube.
- u Explain that the patient can speak by covering the lumen of the tracheostomy tube with a finger or a tracheostomy plug.
- u Advise the patient to wear a medical identification necklace or bracelet indicating the presence of the tracheostomy.
- u Suggest that the patient wear a loosely woven scarf or closed shirt to cover the stoma to warm and filter the inspired air.
- u Instruct the patient to avoid swimming or showering to prevent aspiration.

INTRODUCTION

The largest and heaviest body system—the skin and its appendages (the hair, nails, and certain glands)—performs many vital functions. They protect the inner organs, bones, muscles, and blood vessels; help to regulate body temperature; and provide sensory information. They also prevent body fluids from escaping and eliminate body wastes through more than 2 million pores.

Two layers of skin (integument), the epidermis and dermis, lie above a third layer of subcutaneous tissue. Numerous epidermal appendages exist throughout the skin, including hair, nails, sebaceous glands, and two types of sweat glands: eccrine glands (located over most of the body except the lips) and apocrine glands (found in the axilla and groin near hair follicles). The integumentary system covers an area of 10% to 21½ ft² (1 to 2 m²) and accounts for about 15% of body weight.

Epidermis

The epidermis, the outermost skin layer, varies in thickness from less than 0.1 mm on the eyelids to more than 1 mm on the palms and soles. It's composed of avascular, stratified squamous (scaly or platelike) epithelial tissue that contains multiple layers: a superficial, keratinized, horny layer of cells (stratum corneum)—composed of several layers of cells in various stages of change as they migrate upward—and a deeper, germinal (basal cell) layer.

Stratum corneum

After mitosis occurs in the basal cell layer, epithelial cells undergo a series of changes as they migrate to the outermost part of the stratum corneum, made up of tightly arranged layers of cellular membranes and keratin. Interspersed among the keratinized cells below the stratum corneum are the specialized Langerhans' cells. These cells have a function in the immune response and assist in the initial processing of antigens that enter the epidermis. Epidermal cells usually are shed from the surface as epidermal dust. Differentiation of cells from the basal cell layer to the stratum corneum takes up to 28 days.

Basal cell layer

The basal cell layer produces new cells to replace the superficial keratinized cells that are continuously shed or worn away. The layer's deepest part contains melanocytes, which produce the brown pigment melanin and disperse it to the surrounding epithelial cells. Melanin primarily serves to filter ultraviolet radiation (light). Exposure to ultraviolet light can stimulate melanin production.

Dermis

The second layer of skin, the dermis—or corium—is an elastic system that contains and supports blood vessels, lymphatic vessels, nerves, and epidermal appendages (hair, nails, and eccrine and apocrine glands). The dermis consists of two layers: the superficial papillary dermis and the reticular dermis.

The papillary dermis is studded with fingerlike projections (papillae) that nourish the epidermal cells. The epidermis lies over these papillae and bulges downward to fill the spaces. A collagenous membrane known as the basement membrane lies between the epidermis and dermis, holding them together.

The reticular dermis covers a layer of subcutaneous tissue (adipose layer, or panniculus adiposus), a specialized layer primarily composed of fat cells. It insulates the body to conserve heat, acts as a mechanical shock absorber, and provides energy.

Intercellular material called matrix makes up most of the dermis. Matrix contains connective tissue fibers called collagen, elastin, and reticular fibers. Collagen, a protein, gives strength to the dermis; elastin makes the skin pliable; and reticular fibers bind the collagen and elastin together.

The matrix and connective tissue fibers are produced by spindle-shaped connective tissue cells (dermal fibroblasts), which become part of the matrix as it forms. Fibers are loosely arranged in the papillary dermis but more tightly packed in the deeper reticular dermis.

Epidermal appendages

The epidermal appendages include hair, nails, sebaceous glands, eccrine glands, and apocrine glands.

Hair

Hairs are long, slender shafts composed of keratin. Each hair has an expanded lower end (bulb or root) indented on its undersurface by a cluster of connective tissue and blood vessels called a hair pilus. Each lies within an epithelium-lined sheath called a hair follicle. A bundle of smooth-muscle fibers (arrector pili) extends through the dermis to attach to the base of the hair follicle. Contraction of these muscle fibers causes the hair to stand on end. Hair follicles also have a rich blood and nerve supply.

Nails

Like hair, nails are composed mainly of keratin. They're situated over the distal surface of the end of each digit. The nail plate, surrounded on three sides by the nail folds (cuticles), lies on the nail bed; the germinative nail matrix, which extends proximally for about 5 mm beneath the nail fold, forms the plate. The distal portion of the matrix shows through the nail as a pale, semilunar area (the lunula). The translucent nail plate distal to the lunula exposes the nail bed. The vascular bed imparts the characteristic pink appearance under the nails.

Sebaceous glands

The sebaceous glands are found on all skin parts except for the palms and the soles. They occur predominantly on the scalp, face, upper torso, and anogenital region. Sebum, a lipid substance, is produced by the sebaceous glands and secreted in the hair follicle by way of the excretory duct and then exits through the hair follicle opening to reach the skin surface. Sebum may help waterproof the hair and skin and promote the absorption of fat-soluble substances into the dermis. It may also be involved in the production of vitamin D₃ and have some antibacterial function.

Eccrine glands

Eccrine glands are widely distributed, coiled glands that produce an odorless, watery fluid with a sodium concentration equal to that of plasma. A duct from the secretory coils passes through the dermis and epidermis and opens into the skin surface. Eccrine glands in the palms and soles secrete fluid primarily in response to emotional stress. The remaining 3 million eccrine glands respond primarily to thermal stress and effectively regulate temperature.

Apocrine glands

Apocrine glands—located primarily in the axillary and anogenital areas—have a coiled secretory portion that lies deeper in the dermis than the eccrine glands. A duct connects the apocrine glands to the upper portion of the hair follicle. Apocrine glands, which begin to function at puberty, have no known biologic function. Bacterial decomposition of the fluid produced by these glands causes body odor.

Skin functions

The skin performs many functions: protection of underlying structures, sensory perception, temperature and blood pressure regulation, vitamin synthesis, and excretion.

Protection

The epidermis protects against trauma, noxious chemicals, and invasion by microorganisms.

The skin maintains body surface integrity by cell migration and by shedding and can repair surface wounds by intensifying normal cell replacement mechanisms. Regeneration doesn't occur if the dermal layer is destroyed.

The sebaceous glands produce sebum, a mixture of keratin, fat, and cellulose debris. Combined with sweat, sebum forms a moist, oily, acidic film that is mildly antibacterial and antifungal and protects the skin surface.

Sensory perception

To perform sensory perception, sensory nerve fibers carry impulses to the central nervous system. Autonomic nerve fibers carry impulses to smooth muscles in the walls of the dermal blood vessels, to the muscles around the hair roots, and to the sweat glands. Sensory nerve fibers originate in the dorsal nerve roots and supply specific skin areas known as dermatomes. Through these fibers, the skin can transmit various sensations, including temperature, touch, pressure, pain, and itching.

Temperature and blood pressure regulation

Abundant nerves, blood vessels, and eccrine glands within the dermis assist with thermoregulation. When the skin is exposed to cold or a decrease in internal body temperature, the blood vessels constrict in response to stimuli from the autonomic nervous system. This action decreases blood flow through the skin and conserves body heat.

When the skin is too hot or internal body temperature increases, the small arteries in the dermis dilate. Increased blood flow through these vessels reduces body heat. If this doesn't adequately lower temperature, the eccrine glands act to increase sweat production; subsequent evaporation cools the skin. Dermal blood vessels also help regulate systemic blood pressure by vasoconstriction.

Vitamin synthesis

When stimulated by ultraviolet light, the skin synthesizes vitamin D₃ (cholecalciferol).

Excretion

The skin also is an excretory organ: The sweat glands excrete sweat, which contains water, electrolytes, urea, and lactic acid.

Assessing skin color variations
Skin color variations in various areas of the body can indicate a particular condition, as shown below.

gloves when palpating moist lesions.

Diagnostic tests

Several tests may help to identify skin disorders. Diascopy , in which a lesion is covered with a microscopic slide or piece of clear plastic, helps determine whether dilated capillaries or extravasated blood is causing a lesion's redness. Microscopic immunofluorescence identifies immunoglobulins and elastic tissue in manifestations of immune disorders. Phototesting exposes small areas of the patient's skin to ultraviolet A or ultraviolet B light to detect photosensitivity. Phototesting in combination with patch testing is used to evaluate a patient's photosensitivity to compounds placed on the skin (photopatch testing).

Tzanck test requires smearing vesicular fluid or exudate from an ulcer on a glass slide and then staining it with Papanicolaou's, Wright's, Giemsa, or methylene blue stain. When the slide is examined microscopically, the presence of multinucleated giant cells, intranuclear inclusion bodies, and ballooning degeneration confirms herpesvirus infection.

Potassium hydroxide (KOH) test helps to identify fungal skin infections. It requires removing scales from the skin by scraping and then mixing the scales with a few drops of 10% to 25% KOH on a glass slide. After heating the slide, skin cells dissolve, leaving fungal elements visible on microscopic examination.

Gram stains and exudate cultures help to identify the organism responsible for an underlying infection by separating bacteria into two classifications: gram-negative and gram-positive. Although staining provides rapid, valuable diagnostic leads, firm identification must be made by culturing the organisms.

Patch tests are used to identify the cause of allergic contact sensitization.

Skin biopsy determines the histology of cells and may be diagnostic, confirmatory, or inconclusive, depending on the disease.

Bacterial infections

Skin disorders caused by bacterial infection include folliculitis, furunculosis, and carbunclosis; impetigo; and staphylococcal scalded skin syndrome. They're commonly treated with oral or topical antibiotics or both. The prognosis is usually good.

FOLLICULITIS, FURUNCULOSIS, AND CARBUNCULOSIS

Folliculitis—a bacterial infection of the hair follicle—causes the formation of a pustule. The infection can be superficial (follicular impetigo or Bockhart's impetigo) or deep (sycosis barbae). Folliculitis also may lead to the development of furuncles (furunculosis), commonly known as boils, or carbuncles (carbunclosis). These disorders may be recurrent and are particularly troublesome to healthy young adults. The prognosis depends on the severity of the infection and on the patient's physical condition and ability to resist infection.

Causes

The most common cause of folliculitis, furunculosis, or carbunclosis is coagulase-positive *Staphylococcus aureus*. Predisposing factors include an infected wound elsewhere on the body, poor personal hygiene, debilitation, diabetes mellitus, occlusive cosmetics, tight clothes, friction, incorrect shaving technique, exposure to chemicals (cutting oils), and management of skin lesions with tar or with occlusive therapy, using steroids. Folliculitis may be caused by bacteria other than *S. aureus*, especially as a sequela to erythromycin and tetracycline therapy.

Furunculosis commonly follows folliculitis that is exacerbated by irritation, pressure, friction, or perspiration. Carbunclosis develops more slowly and usually follows persistent *S. aureus* infection and furunculosis.

Complications

Untreated furunculosis may lead to cellulitis, which in turn may progress to septicemia if the infection reaches the dermal vascular plexus. This condition occurs most commonly in infants and others with impaired immune status.

In severe cases, these disorders may result in residual scarring.

Assessment findings

The patient history recounts predisposing factors. The patient may complain of pain, erythema, and edema of several days' duration.

In folliculitis, inspection usually reveals pustules on the scalp, arms, and legs in children; on the face of bearded men (sycosis barbae); and on the eyelids (styes). (See [Bacterial skin infection: A question of degree.](#))

Folliculitis may progress to furunculosis, in which the patient complains of hard, painful nodules, usually on the neck, face, axillae, and buttocks. If nodules enlarge and rupture, inspection will reveal discharged pus and necrotic material on the skin surface. Erythema may persist for days or weeks after nodule rupture.

In severe cases of systemic infection and in carbunclosis, vital sign assessment may reveal fever, and the patient may complain of malaise. Inspection reveals lesions that range from tiny, white-topped pustules to large, yellow pus-filled lesions. The patient with carbunclosis will complain of extremely painful, deep abscesses that drain through multiple openings onto the skin surface, usually around several hair follicles. Palpation is used to detect pain, tenderness, and edema around the pustule sites; in both furunculosis and carbunclosis, it also reveals hard nodules under the skin surface.

A systemic response to the infection may include localized lymphadenopathy.

Diagnostic tests

Wound culture shows *S. aureus*. A complete blood count may reveal an elevated white blood cell count (leukocytosis).

Treatment

Treatment, with emphasis on site care and drug therapy, includes:

- u cleaning the infected area thoroughly with soap and water
- u applying hot, wet compresses to promote vasodilation and drainage from the lesions
- u administering topical antibiotics, such as mupirocin and clindamycin or erythromycin solution
- u administering systemic antibiotics (cephalosporin or dicloxacillin) in extensive infection and in carbunclosis.

Patients with furunculosis also may require incision and drainage of ripe lesions after application of hot, wet compresses and topical antibiotics after drainage.

Nursing diagnoses

- u Body image disturbance
- u Impaired skin integrity
- u Impaired tissue integrity
- u Knowledge deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient will exhibit improved or healed wounds or lesions.
- u The patient will report feelings of increased comfort.
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate the skin care regimen.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Be alert for possible reactions to systemic antibiotic therapy, which may include gastric disturbances and sensitivity reactions.
- u Change the dressing frequently and maintain aseptic technique; to prevent the spread of infection, properly dispose of contaminated dressings and use universal precautions.
- u Assess for patient discomfort, and apply warm, moist compresses to aid suppuration.
- u Encourage the patient to verbalize feelings about his appearance. Recognize the importance of body image.
- u Assist with general hygiene and comfort measures as needed.
- u Administer pain medications and antibiotics as ordered and monitor the patient's response.

Bacterial skin infection: A question of degree

The degree of hair follicle involvement in bacterial skin infection ranges from superficial folliculitis (erythema and a pustule in a single follicle) to deep folliculitis (extensive follicle involvement), to furunculosis (red, tender nodules that surround follicles with a single draining point) and, finally, to carbunculosi s (deep abscesses that involve several follicles with multiple draining points).

Patient teaching

- u Teach the patient and family members meticulous hand-washing technique, and encourage the patient to take daily baths with bactericidal soap to prevent the spread of infection.
- u Teach the patient and family members how to apply warm compresses, change dressings with aseptic technique, and properly dispose of contaminated dressings.
- u Stress the importance of not squeezing lesions to prevent the spread of infection to surrounding areas and to minimize scarring.
- u To avoid spreading bacteria among family members, urge the patient not to share clothes, towels, washcloths, or bed linens and to launder these items in hot water before reusing. Tell him to change his clothes and bedsheets daily.
- u Instruct the patient and family members to continue the entire antibiotic regimen until completed, even if the lesions appear to have healed. Advise them to notify the doctor if adverse reactions to systemic antibiotic therapy occur.
- u Advise the patient with recurrent furunculosis to have a physical examination because an underlying disease such as diabetes mellitus may be present.

ADVANCED PRACTICE

Comparing ecthyma and impetigo

Ecthyma is a superficial skin infection that usually causes scarring. It generally results from infection by beta-hemolytic streptococci.

Ecthyma differs from impetigo in that its characteristic ulcer results from deeper penetration of the skin by the infecting organism (involving the lower epidermis and dermis) and the overlying crust tends to be raised (³/₈ to 1¼ [1 to 3 cm]).

These lesions usually are found on the legs after a scratch or an insect bite. Autoinoculation can transmit ecthyma to other parts of the body, especially to sites that have been scratched open.

Therapy is basically the same as for impetigo, beginning with removal of the crust, but the patient's response may be slower. Parenteral antibiotics also are used.

IMPETIGO

A contagious, superficial skin infection, impetigo (impetigo contagiosa) occurs in nonbullous and bullous forms. This vesiculopustular eruptive disorder spreads most easily among infants, young children, and elderly people. It appears most commonly on the face and other exposed areas, usually around the nose and mouth.

Infants and young children may develop aural impetigo, or otitis externa. These lesions usually clear without treatment in 2 to 3 weeks unless an underlying disorder such as eczema is present. Candidal organisms, additional bacteria, fungi, or viruses may complicate lesions in the diaper area. In addition, impetigo may complicate chickenpox, eczema, and other skin disorders marked by open lesions.

Causes

Bullous impetigo, which starts as a blister, is caused by coagulase-positive *Staphylococcus aureus*. Beta-hemolytic streptococci produce the nonbullous form of

impetigo, which later also may harbor staphylococci, producing a mixed-organism infection.

Predisposing factors, such as poor hygiene, anemia, malnutrition, and a warm climate, favor outbreaks of this infection, which most often occur during the late summer and early fall. The most common transmitters appear to be biting insects, such as mosquitoes and flies, and autoinoculation through scratching.

Complications

A rare but serious complication of streptococcal impetigo is glomerulonephritis, caused by a nephritogenic strain of beta-hemolytic streptococci.

Ecthyma, an ulcerative form of impetigo, may result from deeper skin penetration by the infecting organism. (See [Comparing ecthyma and impetigo.](#))

Assessment findings

The patient history discloses exposure to insect bites or other predisposing factors. Additionally, the patient may relate a history of painless pruritus and burning.

In streptococcal impetigo, inspection typically reveals a small, red macule that has turned into a vesicle, becoming pustular within a few hours. When the vesicle breaks, a characteristic thick, honey-colored crust forms from the exudate. Autoinoculation may cause satellite lesions to appear.

In staphylococcal impetigo, a thin-walled vesicle opens. Inspection finds a thin, clear crust forming from the exudate and a lesion that appears as a central clearing circumscribed by an outer rim—much like a ringworm lesion. Observation commonly reveals these lesions on the face or other exposed areas.

Both forms may appear simultaneously and can be clinically indistinguishable.

Diagnostic tests

A Gram stain of vesicular fluid and visualization under a microscope usually confirms *S. aureus* infection. Culture and sensitivity testing of fluid or denuded skin may indicate the most appropriate antibiotic, but therapy shouldn't be delayed for laboratory results, which can take 3 days. The white blood cell count may be elevated in infection.

Treatment

Measures include broad-spectrum systemic antibiotics (usually a penicillinase-resistant penicillin or erythromycin for patients who are allergic to penicillin). Treatment also includes the removal of the exudate by washing the lesions two to three times a day with soap and water or, for stubborn crusts, using warm soaks or compresses of normal saline or diluted soap solution.

Topical agents, particularly mupirocin, have been used successfully in combination with crust removal with each application.

Antihistamines to alleviate itching and daily bathing with bactericidal soaps as a preventive measure are additional treatments.

Nursing diagnoses

u Body image disturbance u Impaired skin integrity u Impaired tissue integrity u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will exhibit improved or healed wounds or lesions.
- u The patient will report feelings of increased comfort.
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate the skin care regimen.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Use meticulous hand-washing technique and universal precautions to prevent spreading the infection.
- u Cut the patient's fingernails short to prevent scratching, which can cause autoinoculation and new skin breaks.
- u Remove the crusts by gently washing with bactericidal soap and water. Soften stubborn crusts with cool compresses; scrub gently to aid crust removal before applying a topical antibiotic.
- u Give medications as ordered and monitor the patient's response. Remember to check for penicillin allergy.
- u Encourage the patient to verbalize feelings about body image, and acknowledge the importance of body image.

Patient teaching

- u To prevent contagion, emphasize to the patient and family members the importance of meticulous hand-washing technique. Advise parents to cut their child's fingernails short. Encourage frequent bathing with a bactericidal soap. Tell the patient not to share towels, washcloths, and bed linens, which should be kept separate and laundered in hot water before reuse.
- u Teach family members how to identify characteristic lesions. Encourage regular inspections, especially of children, to identify new lesions. If the patient is school-age, notify the school nurse about his condition.
- u Stress the need to continue prescribed medications for 7 to 10 days, even after lesions have healed. Instruct the patient and family members to notify the doctor if adverse effects occur.
- u Provide written instructions for the care of impetiginous lesions, including crust removal, application of topical medications, and dressing change technique.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Staphylococcal scalded skin syndrome is a severe skin disorder marked by epidermal erythema, peeling, and necrosis that give the skin a scalded appearance. This disorder is most prevalent in infants ages 1 to 3 months but may develop in children under age 5; it's uncommon in adults. It follows a consistent pattern of progression, and most patients recover fully. Toxic epidermal necrolysis also presents as a scalded skin syndrome. (See [Understanding toxic epidermal necrolysis.](#))

Causes

Group 2 *Staphylococcus aureus*, primarily phage type 71, is the causative organism in staphylococcal scalded skin syndrome. This penicillinase-producing organism releases epidermolytic toxins that are widely disseminated from a systemic site.

Predisposing factors may include impaired immunity and renal insufficiency, which are present to some extent in the normal neonate because of immature development of these systems. Rarely, this disorder may affect adults undergoing immunosuppressive therapy.

Complications

In 2% to 3% of cases, staphylococcal scalded skin syndrome results in death because of complications of fluid and electrolyte loss, sepsis, and involvement of other

body systems. Septicemia and secondary infections from *Candida* species and gram-negative bacteria also may occur.

Understanding toxic epidermal necrolysis

Toxic epidermal necrolysis (scalded skin syndrome) is a rare, severe skin disorder that causes epidermal erythema, superficial necrosis, and skin erosions. Reepithelialization is slow, and scarring is common. Mortality is high (30%), commonly due to systemic complications, especially among debilitated and elderly patients.

Toxic epidermal necrolysis usually results from a drug reaction, most commonly to butazones, sulfonamides, penicillins, barbiturates, hydantoin, allopurinol, phenolphthalein, and phenylbutazone. It may reflect an immune response or be related to overwhelming physiologic stress or to airborne toxins.

Early symptoms include a burning sensation in the conjunctiva, malaise, fever, generalized skin tenderness, and inflamed mucous membranes. Later signs and symptoms progress through three phases: diffuse, erythematous rash; vesiculation and blistering; and large-scale epidermal necrolysis and desquamation. You may also note large, flaccid bullae that rupture easily, extensive areas of denuded skin, and skin sloughing with slight friction over erythematous areas.

Serum analysis shows leukocytosis, elevated alanine and aspartate aminotransferase levels, and fluid and electrolyte imbalance. Urinalysis indicates albuminuria. Culture and Gram stain of lesions, exfoliative cytology, and biopsy help to rule out infection and other disorders.

Treatment includes high-dose systemic corticosteroids and I.V. fluid replacement. Prophylactic antibiotics may be needed.

Assessment findings

The patient history includes a prodromal upper respiratory tract infection, possibly with concomitant purulent conjunctivitis. Usually, the patient appears profoundly ill. Inspection reveals characteristic lesions. Exfoliation may appear within 24 to 48 hours of onset. Assessment of vital signs typically reveals a fever. Palpation may reveal tenderness over the lesions.

Visible cutaneous changes progress through the following three stages:

- *Erythema*. Becoming visible usually around the mouth and other orifices, erythema may spread in widening circles over the entire body surface.
- *Exfoliation* (24 to 48 hours later). In the more common, localized disease form, superficial erosions and minimal crusting occur, usually around body orifices, and may spread to exposed skin areas. In the more severe disease forms, large, flaccid bullae erupt and may spread to cover extensive body areas. When ruptured, these bullae expose sections of tender, oozing, denuded skin. Intact lesions may not be found because the bullae are fragile; only the erosions may be visible.

At first, the patient with this disorder may appear to be sunburned or to have scarlet fever, but inspection of the mouth shows that he lacks the oral lesions characteristic of scarlet fever.

- *Desquamation*. In this final stage, affected areas dry up and powdery scales form. Normal skin replaces these scales in 5 to 7 days. Residual scarring is rare.

During the initial disease stages, palpation of the affected areas results in Nikolsky's sign (sloughing of the skin when friction is applied). Bullae are so fragile that minimal palpation produces very tender, red, moist areas.

Diagnostic tests

Diagnosis requires careful observation of the three-stage progression of this disease as well as exfoliative cytology and biopsy, which aid in differential diagnosis, ruling out erythema multiforme and drug-induced toxic epidermal necrolysis, both of which are similar to staphylococcal scalded skin syndrome. Isolation of group 2 *S. aureus* on cultures of skin lesions confirms the diagnosis. However, skin lesions sometimes appear sterile.

Blood cultures may be used to recover some causative organisms in very ill patients. If this disorder occurs in a nursery setting, cultures from the nose, throat, and skin breaks of nursing personnel can be used to identify potential carriers of the organism.

Treatment

Systemic antibiotics (usually penicillinase-resistant penicillin) to prevent secondary infections and replacement measures to maintain fluid and electrolyte balance are the most common treatments.

Nursing diagnoses

- Body image disturbance
- Impaired skin integrity
- Ineffective thermoregulation
- Pain
- Risk for fluid volume deficit
- Risk for infection

Key outcomes

- The patient will exhibit improved or healed wounds or lesions.
- The patient will report feelings of increased comfort.
- The patient will avoid or minimize complications.
- The patient and family members will demonstrate the skin care regimen.
- The patient will voice feelings about his changed body image.

Nursing interventions

- Provide special care for the neonate, if required, including placement in an Isolette to maintain body temperature and provide isolation.
- Carefully monitor intake and output to assess fluid and electrolyte balance. In severe cases, provide I.V. fluid replacement as ordered.
- Check vital signs. Be especially alert for a sudden rise in temperature, indicating sepsis, which requires prompt, aggressive treatment.
- Maintain skin integrity. Use strict aseptic technique to preclude secondary infection, especially during the exfoliation stage, because of open lesions. To prevent friction and sloughing of the skin, leave affected areas uncovered or loosely covered. Place cotton between severely affected fingers and toes to prevent webbing.
- Administer warm baths and soaks during the recovery period. Gently debride exfoliated areas.

Patient teaching

- Reassure the parents that complications are rare and residual scars are unlikely.
- Instruct parents to use meticulous hand-washing and aseptic techniques when changing dressings and providing comfort measures, such as warm soaks and baths.
- Stress the importance of avoiding friction on the skin surface during the exfoliation stage and avoiding picking or rubbing scales during the desquamation stage.
- Instruct the parents to contact the doctor if adverse reactions to antibiotic therapy occur. Also explain the importance of completing the entire regimen of antibiotic therapy, even after the lesions appear to have healed.

Fungal infections vary in appearance and include dermatophytosis and tinea versicolor. Complications are minor, and drug therapy, most commonly with topical antifungal agents, usually produces good results.

DERMATOPHYTOSIS

Dermatophytosis (tinea) is a group of superficial fungal infections usually classified according to their anatomic location. Dermatophytosis may affect the scalp (tinea capitis), the bearded skin of the face (tinea barbae), the body (tinea corporis, occurring mainly in children), the groin (tinea cruris, or jock itch), the nails (tinea unguium, also called onychomycosis), and the feet (tinea pedis, or athlete's foot). These disorders vary from mild inflammations to acute vesicular reactions.

Tinea infections are prevalent in the United States and are usually more common in males than in females. Although remissions and exacerbations are common, with effective treatment, the cure rate is very high. About 20% of infected people develop chronic conditions.

Causes

Tinea infections result from dermatophytes (fungi) of the genera *Trichophyton*, *Microsporum*, and *Epidermophyton*. Transmission can occur directly (through contact with infected lesions) or indirectly (through contact with contaminated articles, such as shoes, towels, or shower stalls). Warm weather and tight clothing encourage fungus growth.

Complications

Hair or nail loss and secondary bacterial or candidal infections, resulting in inflammation, itching, tenderness, and maceration, are common complications of tinea infections.

Assessment findings

Tinea lesions vary in appearance and duration. Inspection of the patient with tinea capitis may expose small, spreading papules on the scalp that may progress to inflamed, pus-filled lesions (kerions). Patchy hair loss with scaling may be visible.

Tinea barbae appears as pustular folliculitis in the bearded area.

In *tinea corporis*, inspection and palpation reveal flat skin lesions at any site except the scalp, bearded skin, or feet. These lesions may be dry and scaly or moist and crusty; as they enlarge, their centers heal, producing the classic ring-shaped appearance.

In *tinea cruris*, inspection and palpation find raised, sharply defined, itchy red lesions in the groin that may extend to the buttocks, inner thighs, and external genitalia.

Dermatophytosis of the feet
Dermatophytosis of the feet (tinea pedis) — popularly called athlete's foot — causes macerated, scaling lesions that may spread from the interdigital spaces to the sole. Diagnosis rules out other possible causes of signs and symptoms, including eczema, psoriasis, contact dermatitis, and maceration caused by tight, ill-fitting shoes.

Tinea unguium starts at the tip of one or more toenails (fingernail infection is less common). Inspection reveals gradual thickening, discoloration, and crumbling of the nail, with accumulation of subungual debris. Eventually, the nail may be completely destroyed.

A patient with severe *tinea pedis* may complain of extreme itching and pain on walking. Inspection findings include scaling and blisters between the toes and, possibly, a dry, squamous inflammation that affects the entire sole. (See [Dermatophytosis of the feet.](#))

Diagnostic tests

Potassium hydroxide test and microscopic examination of lesion scrapings usually confirm tinea infection. Wood's light examination may confirm some types of tinea capitis. Culture of the affected area may help to identify the infecting organism.

Treatment

Local tinea infections usually respond to topical antifungal agents, such as imidazole cream or oral griseofulvin for infections of the skin and hair. Oral terbinafine or itraconazole is helpful in nail infection. Topical therapy is effective for tinea capitis; oral griseofulvin for 1 to 3 months is the treatment of choice. In addition to imidazole, other antifungals include naftifine, ciclopirox, terbinafine, haloprogin, and tolnaftate. Topical treatment should continue for 2 weeks after lesions resolve.

Supportive measures include application of open wet dressings, removal of scabs and scales, and administration of keratolytics such as salicylic acid to soften and remove hyperkeratotic lesions of the heels or soles.

Nursing diagnoses

- u Body image disturbance
- u Impaired skin integrity
- u Knowledge deficit
- u Pain
- u Risk for infection

Key outcomes

- u The patient will exhibit improved or healed wounds or lesions.
- u The patient will report feelings of increased comfort.
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate the skin care regimen.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Assess the patient for discomfort and itching. Have the patient's fingernails cut short to minimize skin breaks and the spread of infection from scratching.
- u Be alert for possible adverse reactions to griseofulvin therapy, including sensitivity reactions, GI disturbances, headaches, photosensitivity and, possibly, liver damage.
- u Monitor liver function.
- u For the patient with tinea capitis, discontinue medications and notify the doctor if the condition worsens.
- u Use careful hand-washing technique.
- u For the tinea corporis patient with excessive abdominal girth, use abdominal pads between skin folds, and change the pads frequently. Check the patient daily for excoriated, newly denuded skin areas. Apply open wet dressings two or three times daily to decrease inflammation and help remove scales.
- u For tinea unguium, keep the patient's nails short and straight, and gently remove the debris under the nails. Prepare the patient for prolonged therapy, and explain possible adverse reactions to griseofulvin, which is contraindicated in patients with porphyria and may necessitate an increase in dosage during anticoagulant (warfarin) therapy.

- u For the patient with tinea cruris, provide sitz baths as ordered to relieve itching.

Patient teaching

- u Teach the patient and family members about transmission and recurrence of the infection. Teach them to identify environmental conditions that encourage fungal growth or aggravate the disorder.
- u Advise the patient not to share clothing, hats, towels, bed linens, or pillows with other family members and to keep the lesions covered.
- u Instruct the patient to wear loose-fitting, cotton clothing, which should be changed frequently and laundered in hot water to avoid aggravating the condition.
- u Stress the importance of good hand washing and personal hygiene in preventing the spread of infection.
- u Teach the patient and family members about prescribed medications and preparations. Stress the importance of completing the entire treatment regimen, even after the lesions appear to have healed. Tell them to notify the doctor if adverse reactions occur.
- u Advise the patient to avoid scratching because scarring and secondary infection may occur.
- u If the patient has tinea capitis, suggest that other family members be checked for the disorder.
- u Instruct the patient with tinea cruris to dry the affected area thoroughly after bathing and to dust evenly with antifungal powder. Suggest sitz baths to relieve itching.
- u Recommend that the patient with tinea barbae let his beard grow and trim his whiskers with scissors, not a razor. If he insists that he must shave, advise him to use an electric razor instead of a blade.
- u Encourage the patient with tinea pedis to expose his feet to air whenever possible and to wear sandals or leather shoes and clean cotton socks. Tell him to wash his feet twice daily and, after drying them thoroughly, to dust evenly with an antifungal powder to absorb perspiration and prevent excoriation. In severe infection, the patient may need to disinfect his socks in boiling water.

TINEA VERSICOLOR

Tinea versicolor (pityriasis versicolor) is a chronic, superficial fungal infection that may produce a multicolored rash, commonly on the upper trunk. Primarily a cosmetic defect, it usually affects young people, especially during warm weather, and is most prevalent in tropical countries. Recurrence is common.

Causes

Pityrosporum orbiculare (*Malassezia furfur*) causes tinea versicolor. Whether this condition is infectious or merely a proliferation of normal skin fungi is uncertain.

Complications

Rarely, skin breaks caused by scratching may result in secondary bacterial infections.

Assessment findings

The patient may report seeking medical help because some areas of the body don't tan when exposed to sunlight, causing a cosmetic defect.

Inspection and palpation usually reveal raised or macular, round or oval, slightly scaly lesions on the upper trunk. The lesions may extend to the lower abdomen, neck, arms and, rarely, the face. They usually appear tawny but may range from white (hypopigmented) patches in dark-skinned patients to brown (hyperpigmented) patches in fair-skinned patients. Itching, burning, and inflammation are unusual.

Diagnostic tests

Wood's light examination strongly suggests tinea versicolor. Potassium hydroxide test of skin scrapings confirms tinea versicolor by showing hyphae and clusters of yeast.

Treatment

The most economical and effective treatment is 2.5% selenium sulfide lotion applied once a day for 7 days. The lotion remains on the skin for 10 minutes and then is rinsed off thoroughly. In persistent cases, therapy may require a single 12-hour application of this lotion, followed by weekly washing with an antifungal soap.

More expensive treatments include topical antifungals, such as econazole, ciclopirox, and oral antifungals, such as itraconazole and ketoconazole.

Nursing diagnoses

- u Body image disturbance
- u Impaired skin integrity
- u Knowledge deficit
- u Risk for infection

Key outcomes

- u The patient will exhibit improved or healed wounds or lesions.
- u The patient will avoid or minimize complications.
- u The patient and family members will express an understanding of the disorder and treatment regimen.
- u The patient and family members will demonstrate the skin care regimen.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Have the patient's fingernails cut short to prevent skin breaks caused by scratching, if necessary.
- u Recognize the importance of body image. Encourage the patient to verbalize feelings about his appearance, if appropriate.

Patient teaching

- u Teach the patient meticulous hand-washing technique, and encourage good personal hygiene.
- u Stress the importance of not scratching or picking lesions to avoid the risk of skin breaks and secondary bacterial infections.
- u Provide written instructions for using ordered medications. Tell the patient to contact the doctor if adverse effects occur.
- u Assure the patient that when the fungal infection is cured, discolored areas gradually blend in after exposure to the sun or ultraviolet light.
- u Because recurrence of tinea versicolor is common, advise the patient to watch for new areas of discoloration.

Parasitic infestations

Parasitic infestations are highly contagious and spread rapidly. They're fairly common and respond well to drug therapy. They include cutaneous larva migrans, pediculosis, and scabies.

CUTANEOUS LARVA MIGRANS

Cutaneous larva migrans (also known as creeping eruption) is a skin reaction to infestation by the nematodes (hookworms or roundworms) that usually infect dogs and cats. This parasitic infection most often affects people who come in contact with infected soil or sand, such as children and farmers.

Eruptions associated with cutaneous larva migrans clear completely with treatment.

Causes

Ancylostoma braziliense, the larvae of dog and cat hookworms, is responsible for cutaneous larva migrans. The other dog hookworms, *A. caninum* and *Uncinaria stenocephala*, as well as the human parasites *Strongyloides stercoralis* and *Necator americanus*, also may produce the disease.

Under favorable conditions—warmth, moisture, and sandy soil—hookworm or roundworm ova are present in the feces of affected animals and hatch into larvae, which can then burrow into human skin on contact. After penetrating its host, the larva becomes trapped under the skin, unable to reach the intestines to complete its normal life cycle. It then begins to move around, producing peculiar, tunnel-like, alternately meandering and linear lesions that reflect the nematode's persistent and unsuccessful attempts to escape its host.

Complications

The persistent and intense itching associated with this infestation may lead to tissue trauma, excoriation, crusting, and secondary bacterial infections. In areas with inadequate water and sewage treatment, ingestion of the parasite leads to a more serious condition that involves major body systems.

Assessment findings

The patient history shows contact with warm, moist soil in the past several months.

Inspection discloses transient rash or, possibly, a small vesicle at the penetration point. Penetration usually occurs on an exposed area that has come in contact with the ground, such as the feet, legs, or buttocks. The incubation period may be weeks or months, or the parasite may be active almost as soon as it enters the skin.

Palpation reveals a thin, raised, red line on the skin, which becomes visible as the parasite migrates. This may become vesicular and encrusted as pruritus develops and scratching occurs. The larva's apparently random path can cover from 1 mm to 1 cm a day. Penetration of more than one larva may involve a much larger skin area, marking it with many tracks.

Diagnostic tests

Patient history and clinical observation of the characteristic lesions are diagnostic. No specific diagnostic test exists for this disorder.

Treatment

Cutaneous larva migrans infections may require administration of thiabendazole given orally for 2 or 3 days. Alternatively, a 10% aqueous suspension may be applied topically to avoid systemic toxicity. Oral albendazole for 3 days is effective as an alternative, as is Imervectin in a single dose. Treatment may also include antihistamines to alleviate itching.

Nursing diagnoses

- u Body image disturbance
- u Impaired skin integrity
- u Knowledge deficit
- u Risk for infection
- u Situational low self-esteem

Key outcomes

- u The patient will exhibit improved or healed wounds or lesions.
- u The patient will report feelings of increased comfort.
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate the skin care regimen.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Have the patient's nails cut short to prevent skin breaks and secondary bacterial infection from scratching.
- u Apply cool, moist compresses to alleviate itching.
- u Be alert for possible adverse effects associated with systemic thiabendazole treatment, including nausea, vomiting, abdominal pain, and dizziness.
- u Encourage the patient to verbalize feelings about the infestation, including embarrassment, fear of rejection by others, and body image disturbance. Give reassurance that larva migrans lesions usually clear within 1 to 2 weeks after treatment.

Patient teaching

- u Teach the patient about the existence of the parasites, sanitation of beaches and sandboxes, and proper pet care.
- u Instruct the patient and family members in good hand washing, and stress the importance of preventing the spread of the infection among family members.
- u Explain the importance of adhering to the treatment regimen exactly as ordered. Tell the patient about the possible adverse effects of treatment and to notify the doctor if these occur.

PEDICULOSIS

Any human infestation of parasitic forms of lice is known as pediculosis. It can occur anywhere on the body; the most common kind, pediculosis capitis, feeds on the scalp and, rarely, in the eyebrows, eyelashes, and beard. Pediculosis corporis (body lice) lives next to the skin in clothing seams, leaving only to feed on blood. Pediculosis pubis is found primarily in pubic hairs but also may extend to the eyebrows, eyelashes, and axillary or body hair.

All of these types of lice feed on human blood and lay eggs (nits) in body hairs or clothing fibers. After the nits hatch, the lice must feed within 24 hours or die; they mature in about 2 to 3 weeks. When a louse bites, it injects a toxin into the skin that produces mild irritation and a purpuric spot. Repeated bites cause sensitization to the toxin, leading to more serious inflammation. In severe cases, wheals or a rash may appear on the trunk caused by sensitization to the parasite. Headache, fever, and malaise also may occur, along with the cutaneous changes.

Treatment can effectively eliminate lice.

Causes

Pediculosis capitis (head lice) is caused by *Pediculus humanus* var. *capitis*. *P. humanus* var. *corporis* causes pediculosis corporis (body lice). *Phthirus pubis* causes pediculosis pubis (crab lice). (See [Types of lice](#).)

Pediculosis capitis is usually due to overcrowded conditions and poor personal hygiene. It commonly affects children, especially girls, spreading through shared clothing, hats, combs, and hairbrushes.

Pediculosis corporis is commonly associated with prolonged wearing of the same clothing (which might occur in cold climates), overcrowding, and poor personal

hygiene. It spreads through shared clothing and bedsheets.

Pediculosis pubis is transmitted through sexual intercourse or by contact with clothing, bedsheets, or towels harboring lice.

Complications

Excoriation and secondary bacterial infections from scratching are common complications of pediculosis. Left untreated, pediculosis may result in dry, hyperpigmented, thickly encrusted, scaly skin with residual scarring.

Types of lice		
Head louse	Body louse	Pubic louse
<i>Pediculus humanus</i> var. <i>capitis</i> (head louse) has an appearance similar to that of <i>P. humanus</i> var. <i>corporis</i> .	<i>Pediculus humanus</i> var. <i>corporis</i> (body louse) has a long abdomen, and all its legs are about the same length.	<i>Phthirus pubis</i> (pubic, or crab, louse) is slightly translucent; its first set of legs is shorter than its second and third sets.

Assessment findings

The patient history discloses predisposing factors. In a patient with pediculosis capitis, inspection notes excoriation (with severe itching); matted, foul-smelling, lusterless hair (in severe cases); occipital and cervical lymphadenopathy; and a rash on the trunk, probably caused by sensitization. Hair shafts display oval, gray-white nits, which can't be shaken off as dandruff can.

Inspection of a patient with pediculosis corporis initially exposes red papules (usually on the shoulders, trunk, or buttocks), which change to urticaria from scratching. Nits are found on clothing.

Inspection of the pediculosis pubis patient is used to find skin irritation from scratching that is usually more obvious than the bites. Small, gray-blue spots (maculae ceruleae) may appear on the thighs or upper body. The nits, attached to pubic hairs, feel coarse and grainy.

Diagnostic tests

Wood's light examination achieves fluorescence of the adult lice. Microscopic examination shows nits visible on the hair shaft.

Treatment

For pediculosis capitis, treatment consists of cream rubbed into the hair and rinsed after 10 minutes. A single treatment should be sufficient. Alternatives include pyrethrins and lindane shampoo. A fine-tooth comb dipped in vinegar removes nits from the hair. Washing hair with ordinary shampoo removes crusts.

Clothes and bed linens must be laundered to prevent reinfestation.

Pediculosis corporis necessitates bathing with soap and water to remove lice from the body. In severe infestations, lindane cream may be necessary.

Treatment for pediculosis pubis includes shampooing with lindane shampoo for 4 minutes, and treatment should be repeated in 1 week. Clothes and bed linens must be laundered to prevent reinfestation.

Nursing diagnoses

u Body image disturbance u Impaired skin integrity u Knowledge deficit u Risk for impaired skin integrity u Risk for infection u Situational low self-esteem

Key outcomes

- u The patient will exhibit improved or healed wounds or lesions.
- u The patient will report feelings of increased comfort.
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate the skin care regimen.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Isolate the patient until treatment is complete to prevent spreading the infection.
- u Have the patient's fingernails cut short to prevent skin breaks and secondary bacterial infections caused by scratching.
- u Be alert for possible adverse reactions associated with treatment with antiparasitics, including sensitivity reactions and, in some cases, central nervous system (CNS) toxicity.
- u To prevent self-infestation, avoid prolonged contact with the patient's hair, clothing, and bed sheets. Use gloves, a gown, and a protective head covering when administering delousing treatment.
- u Ask the patient with pediculosis pubis for the names of recent sexual contacts so that they can be examined and treated. If the infestation occurs in a school-age child, notify the school.
- u To prevent the spread of pediculosis to other hospitalized patients, examine all high-risk patients on admission, especially elderly patients who depend on others for care, those admitted from nursing homes, people living in crowded conditions, and homeless people.
- u Encourage the patient to verbalize his feelings about the infestation, including embarrassment, fear of rejection by others, and body image disturbances. Assure the patient and family members that pediculosis can be treated successfully.

Patient teaching

- u Teach the patient and family members how to inspect for and identify lice, eggs, and lesions. Teach them how to decontaminate infestation sources and stress the importance of not borrowing personal articles. Tell parents that if the child's stuffed animals can't be washed, they should be closed in a plastic bag for at least 30 days until all of the nits and eggs have died.
- u Instruct the patient and family members on the use of the creams, lotions, powders, and shampoos that can eliminate lice. Teach them how to remove nits from the hair with a fine-toothed comb and how to use a cotton-tipped applicator to remove lice from eyelashes.
- u Instruct the patient in the proper application of lindane, which can be absorbed by the skin and cause CNS complications. Tell the patient to be alert for possible adverse reactions to treatment and to notify the doctor if these occur.

SCABIES

Scabies—an age-old, highly transmissible skin infestation—is characterized by burrows, pruritus, and excoriations with secondary infections. It occurs worldwide, is associated with overcrowding and poor hygiene, and can be endemic. The mites that cause this disorder can live their entire life cycles in human skin, causing

chronic infection. The female mite burrows into the skin to lay eggs, from which larvae emerge to copulate and then reburrow under the skin.

Causes

Infestation with *Sarcoptes scabiei* var. *hominis* (itch mite) causes scabies. (See [Scabies: Cause and effect.](#))

Transmission of scabies occurs through skin contact or venereally. Schoolchildren, family members, and intimate contacts of those with scabies are at greatest risk for spreading the infection. The adult mite can live for 2 to 3 days without a human host; therefore, inanimate objects can't be ruled out as a means of transmission.

Complications

Persistent pruritus caused by secondary mite sensitization is a complication of scabies. Intense scratching can lead to severe excoriation, tissue trauma, and secondary bacterial infection.

Assessment findings

The history may uncover predisposing factors. The patient may first present with asymptomatic lesions. The patient who's been infected for several weeks will complain of intense itching that becomes more severe at night.

Inspection may reveal characteristic gray-brown burrows, which may appear as erythematous nodules when excoriated. These threadlike lesions, about $\frac{3}{8}$ " (1 cm) long, occur between the fingers, on flexor surfaces of the wrists, on the elbows, in axillary folds, at the waistline, on the nipples in females, and on the genitalia in males. In infants, the burrows (lesions) may appear on the head and neck. Secondary infection may develop, resulting in the formation of papules and vesicles and in crusting.

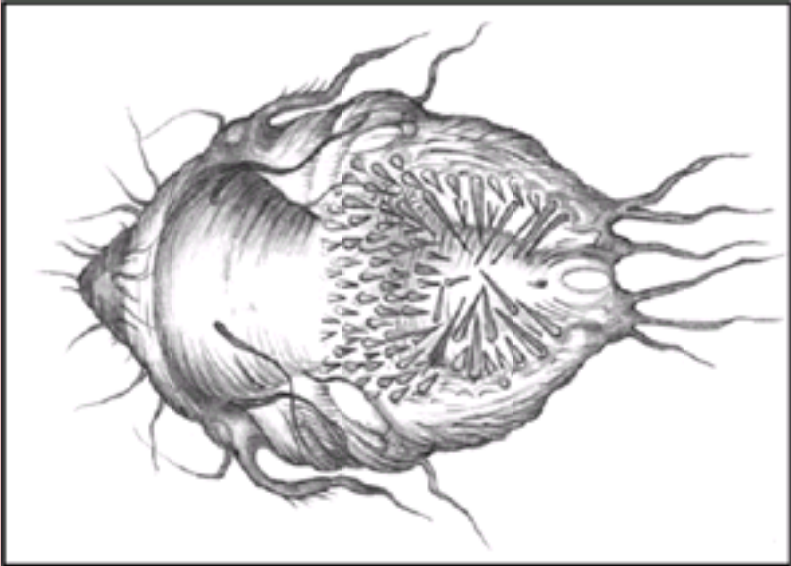

Diagnostic tests

Potassium hydroxide test of burrow scraping may reveal adults, mite feces (called scybala), and eggs. Punch biopsy may help confirm the diagnosis.

If scabies is strongly suspected but diagnostic tests offer no positive identification of the mite, skin clearing with a therapeutic trial of a pediculicide confirms the diagnosis.

Scabies: Cause and effect

Infestation with *Sarcoptes scabiei*—the itch mite—causes scabies. This mite (shown enlarged below) has a hard shell and measures a microscopic 0.1 mm. The second illustration depicts the erythematous nodules with excoriation that appear in patients with scabies.

Treatment

Scabies treatment consists of bathing with soap and water, followed by application of a pediculicide. Permethrin cream (Elimite) or lindane lotion should be applied in a thin layer over the entire skin surface, left on for 8 to 12 hours, and then thoroughly washed off. Because this cream is not ovicidal, application must be repeated in 1 week. Another pediculicide, crotamiton cream, may be applied for 5 consecutive nights but isn't as effective.

Because about 10% of a pediculicide is absorbed systemically, a less toxic 6% to 10% sulfur solution may be applied for 3 consecutive days as an alternative therapy for infants and pregnant women. Secondary bacterial infections may require systemic antibiotics. An antipruritic emollient can reduce itching. Topical steroids, which may potentiate the infection, shouldn't be used.

Nursing diagnoses

- Body image disturbance
- Impaired skin integrity
- Knowledge deficit
- Risk for infection
- Situational low self-esteem

Key outcomes

- The patient will exhibit improved or healed wounds or lesions.
- The patient will report feelings of increased comfort.
- The patient will avoid or minimize complications.

- u The patient and family members will demonstrate the skin care regimen.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Have the patient's fingernails cut short to minimize skin breaks from scratching, which may lead to secondary bacterial infections.
- u To prevent transmission to family members or other patients, isolate the patient until treatment is completed; use meticulous hand washing; observe wound and skin precautions for 24 hours after treatment with a pediculicide; sterilize blood pressure cuffs in a gas autoclave before using them on other patients; isolate linens, towels, clothing, and personal articles until the patient is noninfectious; thoroughly disinfect the patient's room after discharge; and have all contaminated clothing and personal articles washed and disinfected.
- u Suggest that the patient's family and other close personal contacts be checked for symptoms. Have the patient notify sexual contacts. If the patient is school-age, notify the school of his condition.
- u Be alert for complications associated with treatment, including contact dermatitis and hypersensitivity reactions from repeated use of pediculicides. Remember that prolonged use of pediculicides may lead to excessive central nervous system stimulation and seizures.
- u Encourage the patient to verbalize his feelings about the infestation, including embarrassment, fear of rejection by others, and body image disturbance.

Patient teaching

- u Teach the patient and family members to identify characteristic lesions and the modes of transmission. Assure the patient and family members that the infestation can be treated successfully with good hygiene and the use of pediculicides. Stress the importance of meticulous hand washing to prevent the infection's spread and recurrence.
- u Instruct the patient to apply cream or lotion from the neck down, covering the entire body. (He may need assistance to reach all body areas.) Tell him to wait about 15 minutes after application before dressing and to avoid bathing for 8 to 12 hours.
- u Tell the patient not to apply lotion to raw or inflamed skin. Teach him the signs of skin irritation and hypersensitivity reaction. Advise him to notify the doctor immediately, to discontinue using the drug, and to wash the drug from the skin if these signs develop.

Follicular and glandular disorders

Because they affect appearance, follicular and glandular disorders can cause extreme anxiety. Treating patients with these disorders, which include acne vulgaris, alopecia, and rosacea, involves providing reassurance and supportive care.

ACNE VULGARIS

Acne vulgaris is an inflammatory disease of the skin glands and hair follicles. It's characterized by comedones, pustules, nodules, and nodular lesions. This disorder affects nearly 75% of adolescents, although lesions can appear as early as age 8. Boys are affected more often and more severely, but acne occurs in girls at an earlier age and tends to affect them for a longer time, sometimes into adulthood. It tends to run in families. With treatment, the prognosis is good.

Causes

Many factors cause acne. Research now centers on hormonal dysfunction and oversecretion of sebum as possible primary causes.

Acne flare-ups may be associated with the monthly menstrual cycle, stress, trauma, tropical climates, and rubbing from tight clothing. Flare-ups also may be associated with environmental exposure to coal tar derivatives, certain chemicals, cosmetics, or hair pomades.

Certain medications are linked to acne. These include oral contraceptives containing norethindrone and norgestrel; testosterone; anabolic agents; corticotropin; gonadotropins; corticosteroids (prolonged use); iodine- or bromine-containing drugs; trimethadione; phenytoin; isoniazid; lithium; and halothane.

Theories regarding dietary influences (including the nearly universally held “chocolate causes acne” theory) appear to be groundless.

Complications

In severe cases, acne may develop into a deep cystic process with interconnecting channels, gross inflammation, abscess formation, and secondary bacterial infections. Chronic, recurring lesions produce distinctive acne scars.

Assessment findings

The patient history may disclose predisposing factors and seasonal or monthly eruption patterns. Additionally, the history may include pain and tenderness around the area of the infected follicle.

Inspection reveals acne lesions, most commonly on the face, neck, shoulders, chest, and upper back. The area around the infected follicle may appear red and swollen. The acne plug may appear as a closed comedo, or whitehead (if it doesn't protrude from the follicle and is covered by the epidermis), or as an open comedo, or blackhead (if it does protrude and isn't covered by the epidermis). A blackhead's coloration results from the melanin or pigment of the follicle.

The rupture or leakage of an enlarged plug into the dermis produces inflammation and characteristic acne pustules, papules or, in severe forms, acne cysts or abscesses. If the patient has previously picked or squeezed the lesions, scars may be visible.

Diagnostic tests

The presence of characteristic lesions, predisposing factors, and scarring confirms the diagnosis of acne vulgaris.

Treatment

Common therapy for patients with acne includes benzoyl peroxide (a powerful antibacterial) or clindamycin or erythromycin antibacterial agents alone or in combination with tretinoin (retinoic acid or topical vitamin A), a keratolytic. Benzoyl peroxide and tretinoin agents can irritate the skin. Systemic antibiotics such as tetracycline are used to decrease bacterial growth until the patient is in remission; a lower dose is used for long-term maintenance. Exacerbation of pustules or abscesses during either type of antibiotic therapy requires a culture to identify a possible secondary bacterial infection.

ALERT Tetracycline is contraindicated during pregnancy and childhood because it discolors developing teeth. Erythromycin is an alternative for these patients.

Oral tretinoin combats acne by inhibiting sebaceous gland function and keratinization. Because of severe adverse effects, however, the 16- to 20-week course of tretinoin is limited to patients with severe papulopustular or cystic acne or to those who don't respond to conventional therapy.

ALERT Because oral tretinoin is known to cause birth defects, the manufacturer, with Food and Drug Administration approval, recommends pregnancy testing before dispensing, dispensing only a 30-day supply, repeat pregnancy testing throughout the treatment period, effective contraception during treatment, and informed consent of the patient or parents regarding the danger of the drug. A serum triglyceride level should be drawn before therapy with tretinoin begins and at intervals throughout its course.

Female patients may benefit from the administration of birth control pills (such as Ortho-tricycline) or spironolactone because these drugs produce antiandrogenic

effects.

Other treatments for acne vulgaris include intralesional corticosteroid injections.

Nursing diagnoses

- u Body image disturbance
- u Impaired skin integrity
- u Knowledge deficit
- u Risk for infection
- u Situational low self-esteem

Key outcomes

- u The patient will exhibit improved or healed wounds or lesions.
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate the skin care regimen.
- u The patient will voice feelings about his changed body image.
- u The patient and family members will express an understanding of the condition and treatment.

Nursing interventions

- u Assist the patient in identifying and eliminating predisposing factors.
- u Encourage good personal hygiene and the use of oil-free skin care products. Discourage picking or squeezing the lesions to eliminate secondary bacterial infections and scarring.
- u Monitor liver function studies and serum triglyceride levels when tretinoin is used.
- u Be alert for possible complications associated with treatment with systemic antibiotics (such as tetracycline), including sensitivity reactions, GI disturbances, and liver dysfunction.
- u Remember that tetracycline is contraindicated during pregnancy because it discolors the fetus's unerupted teeth.
- u Be alert for possible adverse reactions associated with the use of tretinoin, including possible skin irritation, dry skin and mucous membranes, and elevated triglyceride levels.
- u Encourage the patient with acne to verbalize his feelings, including embarrassment, fear of rejection by others, and body image disturbances. Note the importance of body image in growth and development. Encourage him to develop interests that support a positive self-image and deemphasize appearance.

Patient teaching

- u Explain the causes of acne to the patient and family members. Encourage the patient to seek medical treatment when acne develops.
- u Make sure the patient and family members understand that the prescribed treatment will improve acne more than a strict diet or fanatic scrubbing with soap and water. Dispel myths concerning the influence of diet and sexual activity on the development of acne.
- u Provide written instructions regarding treatment. Instruct the patient receiving tretinoin to apply it at least 30 minutes after washing the face and at least 1 hour before bedtime. Warn against using it around the eyes or lips. Explain that after treatments, the skin should look pink and dry and that some amount of peeling is normal in the morning when tretinoin has been applied at night. Tell the patient that if the skin appears irritated, the preparation may have to be weakened or applied less often. Advise the patient to avoid exposure to sunlight while wearing the solution or to use a sunscreen.
- u If the prescribed regimen includes tretinoin and benzoyl peroxide, advise the patient to avoid skin irritation by using one preparation in the morning and the other at night. Also advise the patient that acne commonly flares up during the early course of treatment, probably because early, developing lesions are uncovered.
- u Instruct the patient to take tetracycline on an empty stomach. Advise him not to take tetracycline with antacids or milk because it interacts with their metallic ions and then is poorly absorbed.
- u Tell the patient taking tretinoin to avoid vitamin A supplements, which can worsen any adverse effects. Warn the patient against giving blood during treatment with this drug and to avoid alcohol ingestion. Also teach how to deal with the dry skin and mucous membranes that usually result during treatment. Instruct the female patient about the severe risk of teratogenicity. Encourage the patient to schedule and follow up with the necessary laboratory studies.
- u Teach the patient and family members techniques to maintain a well-balanced diet, get adequate rest, and manage stress.
- u Inform the patient that acne takes a long time—in some cases, years—to clear. Encourage continued local skin care even after acne clears.

ALOPECIA

Alopecia, more commonly known as hair loss, typically occurs on the scalp; hair loss elsewhere on the body is less common and less conspicuous. In the nonscarring form of this disorder (noncicatricial alopecia), the hair follicle can generally regrow hair. Scarring alopecia usually destroys the hair follicle, making hair loss irreversible.

The most common form of nonscarring alopecia is male-pattern alopecia. Female-pattern alopecia involves diffuse thinning over the top of the scalp. Genetic predisposition commonly influences the time of onset, the degree of baldness, the speed with which it spreads, and the pattern of hair loss.

Other forms of nonscarring alopecia include:

- u *telogen effluvium*, a diffuse alopecia in which numerous hair follicles simultaneously change from the growing anagen phase to the resting telogen phase of the hair growth cycle
- u *alopecia areata* (idiopathic form), a generally reversible and self-limiting disorder most prevalent in young and middle-aged adults of both sexes
- u *trichotillomania*, the compulsive pulling out of one's own hair, most commonly found in children and adolescents.

Causes

Male-pattern alopecia appears to be related to androgen levels and to aging. Predisposing factors of nonscarring alopecia also include radiation, chemotherapy, many types of drug therapies and drug reactions, bacterial and fungal infections, psoriasis, seborrhea, and endocrine disorders, such as thyroid, parathyroid, and pituitary dysfunctions. (See [Cancer drugs that cause alopecia.](#))

Excessive vitamin A can also cause alopecia. Telogen effluvium occurs after childbirth, crash diets (inadequate protein), surgery, severe illness, and high fever.

Scarring alopecia may result from physical or chemical trauma, radiation or chemotherapy, or chronic tension on a hair shaft, such as braiding or rolling the hair. Diseases that produce scarring alopecia include destructive skin tumors, granulomas, lupus erythematosus, scleroderma, follicular lichen planus, and severe bacterial or viral infections, such as folliculitis and herpes simplex.

Complications

Although hair loss has no physiologic complications, it can impair the patient's self-image.

Assessment findings

In male-pattern alopecia, the history reveals predisposing factors and a family history. It also usually reveals a gradual onset of hair loss. The male patient typically describes his hairline as receding and his crown becoming bald. The female patient describes a widening of her part and increasing visibility of her front scalp or crown.

In telogen effluvium, one or more telogen hairs are removed with each pull test. Patients report the loss of about 400 hairs per day, which is four to five times greater than the normal daily hair loss.

In alopecia areata, the history includes a sudden loss of hair. Inspection may reveal small patches of visible scalp or show that the entire scalp is affected (alopecia totalis) or the entire body (alopecia universalis). Although mild erythema may occur initially, affected areas of scalp or skin appear normal. “Exclamation point” hairs (loose hairs with dark, rough, brushlike tips on narrow, less pigmented shafts) occur at the periphery of new patches. Regrowth initially appears as fine, white, downy hair, which is replaced by normal hair.

In trichotillomania, patchy and incomplete areas of hair loss with many broken hairs appear on the scalp but also may occur on other areas such as the eyebrows.

Cancer drugs that cause alopecia
<p>In cancer chemotherapy, certain drugs can cause hair loss, ranging from sporadic thinning to complete baldness. Some drugs damage hair follicles and cause hair roots to atrophy.</p> <p>Mild alopecia</p> <ul style="list-style-type: none">▫ bleomycin (Blenoxane)▫ carmustine (BiCNU)▫ fluorouracil (5-FU)▫ hydroxyurea (Hydrea)▫ melphalan (Alkeran) <p>Moderate alopecia</p> <ul style="list-style-type: none">▫ busulfan (Myleran)▫ etoposide (VP-16)▫ floxuridine, (FUDR)▫ methotrexate (Folex)▫ mitomycin (Mutamycin) <p>Severe alopecia</p> <ul style="list-style-type: none">▫ cyclophosphamide (Cytoxan)▫ daunorubicin (Cerubidine)▫ doxorubicin (Adriamycin)▫ vinblastine (Velban)▫ vincristine (Oncovin)

Diagnostic tests

Pluck or pull test may confirm alopecia. (In this test, the doctor firmly and smoothly tugs a group of 8 to 10 hairs; if more than 4 hairs come out, the patient probably has alopecia.) A microscopic analysis is performed if the pluck or pull test is positive; it shows structural abnormalities or signs of infection.

Wood's lamp examination is used to identify fungal infection. If infected areas glow or fluoresce, the test is positive. The scalp may then be scraped lightly and the scraping viewed under a microscope.

Trichogram discloses the ratio of anagen to telogen hairs. It's used to evaluate the severity and predict the course of hair loss. Biopsy helps to determine the cause of alopecia by pinpointing hair phase and the extent of structural damage.

Diagnosis also must include identifying any underlying disorder.

Treatment

Topical application of minoxidil has limited success in treating male-pattern and female-pattern alopecia, but it's unsuccessful in alopecia areata. Oral finasteride (Propecia) yields better results in both hair retention and new hair growth for some individuals. An alternate treatment is surgical redistribution of hair follicles by autografting.

Patients with alopecia areata may be treated with topical corticosteroids, such as betamethasone dipropionate, halcinonide, and triamcinolone acetonide, or by intralesional injections, which may help to stimulate hair growth if hair loss is confined to small patches; this therapy may produce regrowth in 4 to 6 weeks. Hair loss that persists for more than 1 year has a poor prognosis for regrowth.

Other drug therapy may include photochemotherapy with methoxsalen and ultraviolet light, dermatomucosal agents such as anthralin, antibiotics for bacterial infections, and antifungal agents for fungal infections.

Chemotherapy patients may benefit from procedures that reduce the blood supply to the scalp and thereby preserve more hair structure. These procedures—cold cap application and scalp tourniquet—aren't appropriate for patients with leukemia, lymphoma, or highly metastatic tumors because cancer drugs must be allowed to perfuse the scalp area to irradiate these neoplastic cells.

For some patients, hair transplantation and tunnel grafting or cosmetic interventions (hairpieces, weaving, or bonding) are beneficial.

Telogen effluvium resolves spontaneously over 6 to 12 months.

In trichotillomania, an occlusive dressing promotes normal hair growth by protecting the site of hair loss. The treatment for other types of alopecia varies according to the underlying cause.

Nursing diagnoses

▫ Body image disturbance ▫ Risk for impaired skin integrity ▫ Risk for infection ▫ Situational low self-esteem

Key outcomes

- The patient will remain free from signs and symptoms of infection.
- The patient will express his concerns about the condition.
- The patient will avoid complications.
- The patient will voice feelings about his changed body image.

Nursing interventions

- Reassure the patient with female-pattern alopecia that hair thinning doesn't lead to total baldness. Suggest that she use a wig or hairpiece.
- For the patient undergoing radiation therapy or chemotherapy with drugs that cause alopecia, suggest selecting a hair replacement before treatment.

- u Encourage the patient to express his feelings. Help him develop interests that contribute to a positive self-image.

Patient teaching

- u Explain the familial link in male-pattern alopecia.
- u Inform the patient that a well-balanced diet with adequate protein promotes healthy hair. If alopecia results from excessive vitamin A, advise the patient to avoid vitamin A supplements.
- u Tell the patient that commercial preparations don't restore or promote hair growth.
- u If the patient is receiving topical minoxidil, inform him that 40% of patients report moderate to dense hair growth after 1 year of regular treatment. Caution him that results may not become apparent for 4 or more months. Explain the proper use of the drug and point out that increasing the dose or the frequency of treatment doesn't increase the rate of hair growth. Describe possible adverse effects, and advise him to notify the doctor if they occur.

ALERT Finasteride is contraindicated in women of childbearing potential. Results are usually apparent after 6 months, and therapy must continue indefinitely.

- u Instruct the patient receiving corticosteroids to report signs and symptoms of skin infection, such as redness; pus-filled blisters; pain, burning, itching, or peeling; numbness in the fingers; weight gain; facial puffiness; thinning skin with bruising; and any new hair loss.
- u Advise the patient with alopecia caused by chemotherapy that hair may grow back in a different color or type, such as curly or straight.

ROSACEA

Rosacea is a chronic skin eruption that produces flushing and dilation of small blood vessels in the face, especially the nose and cheeks. Papules and pustules also may appear but without the characteristic comedones of acne vulgaris.

Rosacea is most common in white women between ages 30 and 50. However, when the disorder affects men, it strikes with greater severity and is commonly associated with rhinophyma, which is characterized by dilated follicles and thickened, bulbous skin on the nose. Rosacea usually spreads slowly and seldom subsides spontaneously.

Causes

The cause of rosacea is unknown. Anything that produces flushing—for example, hot beverages, such as tea or coffee; tobacco; alcohol; spicy foods; physical activity; sunlight; and extreme heat or cold—can aggravate rosacea.

Complications

Ocular involvement may result in blepharitis, conjunctivitis, uveitis, or keratitis.

Assessment findings

The patient history reveals predisposing factors or exposure to conditions that aggravate rosacea. On inspection, you see a blush area on the cheeks, nose, forehead, and chin, usually beginning across the central oval of the face. Redness, intermittent at first, later becomes permanent. Telangiectasia may be present along with pustules and papules.

Although rhinophyma commonly accompanies severe rosacea, it may occur alone. It usually appears first on the lower half of the nose and produces red, thickened skin and follicular enlargement.

Diagnostic tests

Rosacea is confirmed by the presence of typical vascular and acneiform lesions without the comedones characteristically associated with acne vulgaris and, in severe cases, by rhinophyma.

Treatment

Oral tetracycline in gradually decreasing doses as symptoms subside is used to treat patients with the acneiform component of rosacea. Topical application of 1% hydrocortisone cream reduces erythema and inflammation. Topical metronidazole is also very effective. Other treatment may include electrosurgery or a laser to destroy large, dilated blood vessels and removal of excess tissue in patients with rhinophyma.

Nursing diagnoses

- u Body image disturbance
- u Risk for infection
- u Impaired skin integrity
- u Knowledge deficit
- u Situational low self-esteem

Key outcomes

- u The patient will exhibit improved or healed wounds or lesions.
- u The patient will report feelings of increased comfort.
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate the skin care regimen.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Be alert for possible sensitivity reactions and GI disturbances that may accompany treatment with systemic antibiotics.
- u Encourage the patient to express his feelings. Offer emotional support and reassurance.

Patient teaching

- u Assist the patient in identifying and eliminating aggravating factors. If stress and anxiety seem to trigger the disease, teach relaxation techniques and encourage him to use them often.
- u Instruct the patient to use meticulous hand washing and personal hygiene to avoid irritating and aggravating the condition. To prevent infection, stress the importance of not picking or squeezing the lesions.
- u Provide directions for antibiotic therapy, and tell the patient to report any adverse effects.

Disorders of pigmentation

Disorders of pigmentation, characterized by a loss or change of skin pigment, include albinism, melasma, photosensitivity reactions, and vitiligo.

ALBINISM

Albinism is an inherited disorder that results from a defect in melanin metabolism of the skin and eyes (oculocutaneous albinism) or just the eyes (ocular albinism).

Ocular albinism impairs visual acuity. Oculocutaneous albinism also causes severe intolerance to sunlight and heightens susceptibility to skin cancer in exposed areas.

Causes and pathophysiology

Oculocutaneous albinism results from an autosomal recessive trait; ocular albinism results from an X-linked recessive trait that causes hypopigmentation only in the iris and the ocular fundus.

Normally, melanocytes (pigment cells) synthesize melanin. Melanosomes, melanin-containing granules within melanocytes, diffuse and absorb the sun's ultraviolet light, thus protecting the skin and eyes from its dangerous effects.

In tyrosinase-negative oculocutaneous albinism (most common), melanosomes don't contain melanin because they lack tyrosinase, the enzyme that stimulates melanin production. In tyrosinase-positive oculocutaneous albinism, melanosomes contain tyrosine, a tyrosinase substrate, but a defect in the tyrosine transport system impairs melanin production. In tyrosinase-variable albinism (rare), an unidentified enzyme defect probably impairs synthesis of a melanin precursor.

Tyrosinase-negative albinism affects about 1 in every 34,000 persons in the United States and strikes whites and blacks equally. Tyrosinase-positive albinism strikes more blacks than whites. Native Americans have a high incidence of both forms.

Complications

Lack of pigmentation in the eyes may result in nystagmus, photosensitivity, and errors of refraction. Some patients develop pigmented nevi, which require surgical removal. Other complications include actinic keratosis and increased susceptibility to skin cancer.

Assessment findings

Family history reveals albinism. In light-skinned white patients with tyrosinase-negative albinism, inspection shows pale skin, hair that is white to yellow, and pupils that appear red because of translucent irides.

CULTURAL TIP Blacks with albinism have hair that may be white, faintly tinged with yellow, or yellow-brown. The hair and skin of both whites and blacks with tyrosinase-positive albinism grow darker as they age. For instance, their hair may become straw-colored or light brown and their skin cream-colored or pink. Inspection of patients with tyrosinase-positive albinism may reveal freckles and pigmented nevi that may require excision.

Diagnostic tests

Microscopic examination of the skin and of hair follicles is used to determine the amount of pigment present. Pigmentation testing of plucked hair roots by incubating them in tyrosinase distinguishes tyrosinase-negative albinism from tyrosinase-positive albinism. Tyrosinase-positive hair bulbs develop color.

Treatment

No treatment exists. Therapy consists of preventive measures to avoid skin damage from sunlight and supportive measures to help the patient and family members cope with social and emotional problems.

Nursing diagnoses

- u Body image disturbance
- u Knowledge deficit
- u Risk for impaired skin integrity
- u Situational low self-esteem

Key outcomes

- u The patient and family members will express an understanding of the disorder and treatment.
- u The patient and family members will verbalize their feelings and concerns about the condition.
- u The patient will voice feelings about his changed body image.
- u The patient will avoid complications.

Nursing interventions

- u Encourage the patient to express his concerns about body image. Answer his questions, and stay with him during periods of anxiety. Discuss his embarrassment and fear of rejection by others.
- u Offer emotional support and reassurance. Help the patient develop interests that support a positive self-image and deemphasize appearance.
- u If the patient and family members experience difficulty adjusting to the patient's appearance, advise them to seek counseling to develop effective coping strategies.

Patient teaching

- u Advise the patient to wear full-spectrum sunblocks, dark glasses, and appropriate protective clothing when exposed to sunlight.
- u Inform the patient about cosmetic measures (glasses with tinted lenses, makeup) that can alter appearance.
- u Stress the need for frequent refractions and eye examinations to correct visual defects.
- u Advise family members that genetic counseling can provide information about the probability of albinism's recurrence in future offspring.

MELASMA

Melasma is a patchy, hypermelanotic skin disorder that causes a serious cosmetic problem. It tends to occur equally in all races, but the light-brown color characteristic of melasma is most visible on dark-skinned whites. Melasma (also called chloasma or mask of pregnancy) affects women more often than men. It may be chronic but is never life-threatening.

Causes

The cause of melasma is unknown. Histologically, hyperpigmentation results from increased melanin production, although the number of melanocytes remains normal. Melasma may be related to the increased hormonal levels associated with pregnancy, ovarian cancer, and the use of oral contraceptives. Progestational agents, phenytoin, and mephenytoin may also contribute to this disorder. Exposure to sunlight stimulates melasma, but the condition may develop without any apparent predisposing factor.

Complications

Untreated melasma produces no complications.

Assessment findings

The patient history may reveal predisposing factors. Inspection may show large, brown, irregular patches symmetrically distributed on the forehead, cheeks, and sides of the nose. You may also note patches on the patient's neck, upper lip, and temples, although these occur less commonly.

Diagnostic tests

Observation of characteristic dark patches on the face usually confirms melasma.

Treatment

The primary treatment is the application of a bleaching agent containing 2% to 4% hydroquinone to inhibit melanin synthesis. This medication is applied twice daily for up to 8 weeks. Adjunctive measures include avoiding exposure to sunlight, using sunscreens, and discontinuing oral contraceptives.

Nursing diagnoses

- u Body image disturbance
- u Knowledge deficit
- u Situational low self-esteem

Key outcomes

- u The patient and family members will express an understanding of the disorder and treatment.
- u The patient and family members will verbalize their feelings and concerns about the condition.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Help the patient to identify and eliminate predisposing factors.
- u Encourage the patient to express feelings about her body image, including any feelings of embarrassment or fear of rejection. Offer reassurance when appropriate.

Patient teaching

- u Advise the patient to avoid exposure to the sun by using sunscreens and wearing protective clothing.
- u Inform the patient that bleaching agents may help mask melasma but may require repeated treatments to maintain the desired effect.
- u Mention that cosmetics also may help mask deep pigmentation.
- u Make sure the patient knows the proper method of applying bleaching agents and the possible adverse effects associated with them (erythema, stinging, or other sensitivity reactions). Advise her to call the doctor if such reactions occur and persist.
- u Reassure the patient that melasma is treatable. It may fade spontaneously with protection from sunlight, postpartum, and after discontinuing oral contraceptives. Serial photographs can be used to show the patient that patches are improving.

PHOTOSENSITIVITY REACTIONS

An adverse reaction to natural or artificial light or to light and certain chemicals (including some medications) characterizes photosensitivity reactions. The most common reaction is sunburn, which is dose-related. The other two types are phototoxic reactions, which are also dose-related, and photoallergic reactions, which are uncommon and not dose-related—even slight exposure can cause a severe reaction.

Causes

Sunburn results from unprotected exposure to the sun's ultraviolet rays. (See [How ultraviolet rays damage the skin.](#))

A phototoxic reaction results from exposure to sunlight teamed with certain medications, such as antihistamines and antimicrobials, or chemicals, such as dyes, coal tar, and furocoumarin compounds found in plants. Some foods, such as celery, parsnips, carrots, and limes, that touch the patient's skin while in the sun can cause a phototoxic reaction. Berlock dermatitis, a specific photosensitivity reaction, results from the use of oil of bergamot—a common component of perfumes, colognes, and pomades.

A photoallergic reaction is an immune response that can arise after even slight exposure to light.

Risk factors associated with photosensitivity include:

- u outdoor occupation
- u outdoor lifestyle
- u youth or age
- u certain environmental factors (high altitude or proximity to equator)
- u decreased ozone layer density.

Complications

Repeated photosensitivity reactions, especially sunburn, may eventually cause premature aging of the skin (wrinkling and a dry, leathery appearance) and skin cancer. The burning and itching that accompany a photosensitivity reaction may cause scratching, which can lead to skin breaks and secondary bacterial infections.

Assessment findings

The sunburned patient typically reports recent exposure to ultraviolet rays and may complain of burning and itching in sun-exposed areas. Inspection may reveal skin redness, swelling, blistering, and peeling.

In a phototoxic reaction, the patient may report that immediately after exposure to an allergen or toxic compound, he felt a burning sensation followed by erythema, edema, desquamation, and hyperpigmentation. In berlock dermatitis, the patient may describe an acute reaction that produced erythematous vesicles that later became hyperpigmented.

Photoallergic reactions may take one of two forms. In polymorphous light eruption, the patient may report that he began developing signs and symptoms 2 to 5 hours after sun exposure. Inspection of the skin may reveal erythema, papules, vesicles, urticaria, and eczematous lesions; pruritus may persist for 1 to 2 weeks. In solar urticaria, the patient may report that his skin began to itch and burn after only a few minutes' exposure to the sun and that the symptoms lasted about an hour. Inspection of the skin after that time may reveal erythema and wheals.

Diagnostic tests

The Photopatch test for ultraviolet A and B (UVA and UVB) rays may aid the diagnosis and identify the causative light wavelength. Skin punch biopsy helps to diagnose skin damage resulting from the sun.

Other studies must rule out connective tissue disease, such as lupus erythematosus and porphyrias.

Treatment

For many photosensitive patients, treatment focuses on prevention by using a sunscreen, wearing protective clothing, and limiting exposure to sunlight. (See [Categorizing photosensitivity.](#)) For other patients, progressive exposure to sunlight can thicken the skin and produce a tan that interferes with photoallergens and

prevents further eruptions.

PUVA (psoralen and UVA) may be used to treat polymorphous light eruption. Treatment for solar urticaria may also require PUVA. Although hyperpigmentation usually fades in several months, hydroquinone preparations can hasten the process.

Nursing diagnoses

- u Body image disturbance
- u Knowledge deficit
- u Risk for fluid volume deficit
- u Risk for impaired skin integrity
- u Risk for infection

Key outcomes

- u The patient will exhibit adequate fluid volume.
- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will avoid or minimize complications.
- u The patient and family members will express an understanding of the disorder and treatment.

How ultraviolet rays damage the skin

Exposure to the sun's rays age the skin in several ways.

Superficial skin damage

The sun's ultraviolet B rays penetrate superficial skin, causing the outermost layer to burn, blister, dry, and peel. These rays also change and darken the protective melanin in epidermal cells. In response to the damage, blood volume in the area increases, resulting in red, swollen, sore skin that is painful to the touch.

Connective tissue damage

Meanwhile, ultraviolet A rays penetrate deeper into connective tissue, damaging the proteins that keep the skin flexible and youthful looking. These rays may also inhibit the enzymes necessary to repair the cells damaged by ultraviolet B rays, contributing to skin cancer.

Further damage

Eventually, ultraviolet rays cause further skin changes, including loss of elasticity and a diminished vascular network. The result is thick, wrinkled skin at best and skin cancer at worst.

Nursing interventions

- u Help the patient to identify possible causative agents.
- u Discourage picking, squeezing, or scratching of skin lesions to prevent secondary bacterial infection.
- u Apply cool, moist compresses to provide relief from itching and burning.
- u Be alert for adverse reactions associated with PUVA treatment, such as localized burning, pruritus, nausea, and squamous cell epitheliomas. Applying hydroquinone preparations to hyperpigmented areas may also cause skin irritation and burning.
- u Encourage the patient to express his feelings about his body image and other concerns.

Patient teaching

- u Teach the patient to check his skin frequently for signs of skin cancer. Tell him to report any mole that has changed in color, size, or shape; any mole with irregular borders; any persistent, waxy lumps or rough, red patches; or any sore that won't heal.
- u Encourage the patient to drink plenty of fluids whenever he's in the sun and anytime he has a sunburn to replenish fluid lost through perspiration and dehydration.
- u Provide written instructions for the use of PUVA and hydroquinone preparations.
- u Explain the different types of sunscreens and their degree of protection and help the patient choose an appropriate sunscreen. Advise him to pick one that protects against both UVA and UVB radiation and that contains para-aminobenzoic acid (PABA) or a PABA substitute (benzophenone, cinnamate, and salicylate) and titanium dioxide. Explain that these ingredients offer the best protection against skin damage and skin cancer.
- u Encourage the patient to limit his amount of sun exposure between 10 a.m. and 3 p.m. If he must be in the sun during these hours, suggest that he wear protective clothing, such as long-sleeved shirts and long pants of tightly woven, dark fabrics.

Categorizing photosensitivity	
The American Academy of Dermatology categorizes photosensitivity by skin types that range from I to VI. A patient with fair, sensitive skin has skin type I; a patient with dark, insensitive skin has skin type VI. Use the following chart to estimate your patient's photosensitivity. Then follow this rule of thumb for choosing sunscreens with numbered sun protection factors: The fairer the patient's skin, the higher the sun protection factor needed.	
SKIN TYPE	SUN EXPOSURE HISTORY
I	Always burns, never tans; extremely sensitive skin
II	Always burns easily, tans slightly; very sensitive skin
III	Sometimes burns, tans gradually to light brown; sensitive skin
IV	Burns slightly, always tans to moderate brown; minimally sensitive skin
V	Rarely burns, tans well; insensitive skin
VI	Never burns, deep pigmentation; insensitive skin

VITILIGO

Vitiligo is characterized by stark-white skin patches that may cause a serious cosmetic problem. It results from the destruction and loss of melanocytes (pigment cells). This condition affects about 1% of the U.S. population, usually people between ages 10 and 30, with peak incidence around age 20. It shows no racial preference, but

the distinctive patches are most prominent in blacks. Vitiligo doesn't favor either sex; however, women tend to seek treatment more often than men. Repigmentation therapy may necessitate several summers of exposure to sunlight; the effects of this treatment may be temporary.

Causes

The cause of vitiligo is unknown. One theory implicates an autoimmune process that destroys existing melanocytes. Even at the periphery of lesions, melanocytes appear abnormal and in various stages of cell demise. Melanocytes may migrate from residual areas, such as hair follicles, and repigment lesions.

Other theories implicate enzymatic self-destructing mechanisms and abnormal neurogenic stimuli. Heredity may play a role: About 30% of patients with vitiligo have family members with the same condition.

Some link exists between vitiligo and several other disorders that it commonly accompanies: thyroid dysfunction, pernicious anemia, Addison's disease, aseptic meningitis, diabetes mellitus, photophobia, hearing defects, alopecia areata, and halo nevi.

The most common precipitating factor is a stressful physical or psychological event, such as severe sunburn, surgery, pregnancy, loss of a job, and bereavement. Chemical agents, such as phenols and catechols, may also cause this condition.

Complications

Common complications include extreme photosensitivity in depigmented areas. Patients may also develop hypersensitivity reactions to therapeutic agents and to the dyes or cosmetics used to camouflage the lesions.

Assessment findings

Family history may reveal vitiligo as well as a precipitating factor. Inspection may find depigmented or stark-white skin patches that are almost imperceptible on fair-skinned whites. These patches are usually bilaterally symmetrical, with distinct borders that may be raised and hyperpigmented. These patches are most likely seen over bony prominences, around orifices (eyes, mouth), within body folds, and at sites of traumatic injury. Hair within these lesions may also be white. Because hair follicles and certain eye parts also contain melanocytes, inspection may reveal prematurely gray hair and ocular pigment changes.

Diagnostic tests

In fair-skinned patients, Wood's light examination in a darkened room is used to detect vitiliginous patches: Depigmented skin reflects the light; pigmented skin absorbs it.

If autoimmune or endocrine disorders are suspected, laboratory studies are appropriate.

Other skin disorders, such as tinea versicolor, must be ruled out.

Treatment

Repigmentation therapy combines systemic or topical psoralen compounds, or both, with exposure to sunlight or artificial ultraviolet A (UVA) light. New pigment rises from hair follicles and appears on the skin as small freckles, which gradually enlarge and coalesce. Body parts that contain few hair follicles (such as the fingertips) may resist this therapy.

Because psoralens and UVA affect the entire skin surface, systemic therapy enhances the contrast between normal skin, which turns darker than usual, and white, vitiliginous skin. The use of sunscreen on normal skin may minimize the contrast while preventing sunburn.

Depigmentation therapy is suggested for patients with vitiligo that affects more than 50% of the body surface. A cream containing 20% monobenzone permanently destroys melanocytes in unaffected skin areas and produces a uniform skin tone. This medication is applied initially to a small area of normal skin once daily to test for unfavorable reactions. If no such reactions occur, the patient begins applying the cream twice daily to those areas he wants to depigment first. Eventually, the entire skin may be depigmented to achieve a uniform color. Depigmentation is permanent and results in extreme photosensitivity.

Commercial cosmetics may help deemphasize vitiliginous skin. Some patients prefer dyes because they remain on the skin for several days.

Nursing diagnoses

u Body image disturbance u Knowledge deficit u Risk for impaired skin integrity u Situational low self-esteem

Key outcomes

- u The patient and family members will express an understanding of the disorder and treatment.
- u The patient and family members will verbalize their feelings and concerns about the condition.
- u The patient will voice feelings about his changed body image.
- u The patient will avoid complications.

Nursing interventions

- u Encourage the patient to express his feelings about his appearance. Offer emotional support and reassurance, but avoid promoting unrealistic hope for a total cure.

Patient teaching

- u Explain the disorder to the patient, and answer his questions.
- u In repigmentation therapy, instruct the patient to use psoralen medications three or four times weekly.

ALERT Tell patients to take systemic psoralens 2 hours before exposure to sun. Topical solutions should be applied 30 to 60 minutes before exposure.

- u Remind patients undergoing repigmentation therapy that exposure to sunlight also darkens normal skin. After being exposed to UVA for the prescribed amount of time, the patient should apply a sunscreen if he plans to be exposed to sunlight also. If sunburn occurs, advise the patient to discontinue the therapy temporarily and to apply open wet dressings (using thin sheeting) to affected areas for 15 to 20 minutes four or five times daily or as necessary for comfort. After applying wet dressings, the patient should allow the skin to air dry. Suggest that he apply a soothing lubricating cream or lotion while the skin is still slightly moist.
- u Suggest that the patient receiving depigmentation therapy wear protective clothing and use a sunscreen (sun protection factor [SPF] 15). Explain the therapy thoroughly, and allow the patient plenty of time to decide whether to undergo this treatment. Make sure he understands that the results of depigmentation are permanent and that he must thereafter protect his skin from the adverse effects of sunlight.
- u Warn the patient to use a sunscreen (no less than SPF 15) to protect both affected and normal skin during exposure to sun and to wear sunglasses after taking the medication. If periorbital areas require exposure, tell the patient to keep his eyes closed during treatment.
- u Caution the patient about buying commercial cosmetics or dyes without trying them first because some may not be suitable.

Inflammatory reaction

An inflammatory reaction (characterized by redness, swelling, and itching of the skin) may be short-lived or lead to scarring and other permanent skin changes.

DERMATITIS

Dermatitis is characterized by inflammation of the skin and can be acute or chronic. It occurs in several forms, including contact, seborrheic, nummular, exfoliative, and stasis dermatitides. (See [Types of dermatitis.](#))

Atopic dermatitis (discussed here), also commonly referred to as atopic or infantile eczema, neurodermatitis constitutionalis, or Besnier's prurigo, is a chronic inflammatory response often associated with other atopic diseases, such as bronchial asthma, allergic rhinitis, and chronic urticaria. It usually develops in infants and toddlers between ages 6 months and 2 years, commonly in those with strong family histories of atopic disease. These children typically acquire other atopic disorders as they grow older. In most cases, this form of dermatitis subsides spontaneously by age 3 and remains in remission until prepuberty (ages 10 to 12), when it flares up again. The disorder affects about 9 out of every 1,000 people.

Causes

Although the exact cause of atopic dermatitis is unknown, several theories attempt to explain its pathogenesis. One theory suggests an underlying metabolically or biochemically induced skin disorder genetically linked to elevated serum immunoglobulin E (IgE) levels. Another theory suggests defective T-cell function.

Atopic dermatitis is exacerbated by certain irritants, infections (commonly *Staphylococcus aureus*), and allergens. Common allergens include pollen, wool, silk, fur, ointment, detergent, perfume, and certain foods, particularly wheat, milk, and eggs. Flare-ups may occur in response to temperature extremes, humidity, sweating, and stress.

Complications

Without proper treatment, dermatitis can cause permanent skin damage, including lichenification (thickening and hardening of the skin with exaggerated normal markings), altered pigmentation, and scarring. Uncontrolled atopic dermatitis increases the patient's susceptibility to bacterial, fungal, and viral infections. In turn, certain viral infections, such as vaccinia and herpes simplex, can lead to Kaposi's varicelliform eruption, which can be fatal.

Assessment findings

The patient history typically reveals a family history of atopic dermatitis as well as exposure to an allergen or irritant. The patient typically complains of intense itching.

Early in the course of atopic dermatitis, inspection of the skin may reveal erythematous patches in excessively dry areas. In children, look for these lesions on the forehead, cheeks, and extensor surfaces of the arms and legs; in adults, look at flexion points (antecubital fossa, popliteal area, and neck). During a flare-up, you may note edema, scaling, and vesiculation because of scratching; the vesicles may be pus-filled. In chronic disease, you may observe multiple areas of dry, scaly skin with white dermatographism, blanching, and lichenification.

The distribution of skin lesions in atopic dermatitis rules out other inflammatory skin lesions, such as diaper rash (lesions confined to the diapered area), seborrheic dermatitis (no pigmentation changes or lichenification in chronic lesions), and chronic contact dermatitis (lesions affecting hands and forearms, sparing antecubital fossa and popliteal areas).

Diagnostic tests

Firm stroking of the patient's skin with a blunt instrument will cause a white—not reddened—dermatographism (hive) to appear on the skin of 70% of patients with atopic dermatitis. Patch testing and inspecting the distribution of lesions helps pinpoint the provoking allergen.

A food elimination diet, although seldom revealing the primary cause of atopic dermatitis, may help to identify at least one allergen.

Types of dermatitis				
TYPE	CAUSES	ASSESSMENT FINDINGS	DIAGNOSIS	CHRONIC DERMATITIS

Chronic dermatitis

Characterized by inflammatory eruptions of the hands and feet

- Usually unknown but may result from progressive contact dermatitis
- Secondary factors: trauma, infections, redistribution of normal flora, photosensitivity, and food sensitivity, which may perpetuate this condition

- Thick, lichenified, single or multiple lesions on any part of the body (commonly on the hands)
- Inflammation and scaling
- Recurrence after long remissions

- No characteristic pattern or course; diagnosis based on detailed history and physical findings

- Elimination of known allergens and decreased exposure to irritants, wearing protective clothing such as gloves, and washing immediately after contact with irritants or allergens
- Antibiotics for secondary infection
- Avoidance of excessive washing and drying of hands and of accumulation of soaps and detergents under rings
- Use of emollients with topical steroids

Contact dermatitis

Often sharply demarcated skin inflammation and irritation due to contact with concentrated substances to which the skin is sensitive, such as perfumes or chemicals

- Mild irritants: chronic exposure to detergents or solvents
- Strong irritants: damage on contact with acids or alkalis
- Allergens: sensitization after repeated exposure

- Mild irritants and allergens: erythema and small vesicles that ooze, scale, and itch
- Strong irritants: blisters and ulcerations
- Classic allergic response: clearly defined lesions, with straight lines following points of contact
- Severe allergic reaction: marked edema of affected areas

- Patient history
- Patch testing to identify allergens
- Shape and distribution of lesions

- Same as for chronic dermatitis
- Topical anti-inflammatory agents (including steroids), systemic steroids for edema and bullae, antihistamines, and local applications of Burow's solution (for blisters)
- Other nursing interventions similar to those for atopic dermatitis

Exfoliative dermatitis

Severe, chronic skin inflammation characterized by redness and widespread erythema and scaling

- Progression of preexisting skin lesions to exfoliative stage, as in contact dermatitis, drug reaction, lymphoma, or leukemia

- Generalized dermatitis, with acute loss of stratum corneum, and erythema and scaling
- Sensation of tight skin
- Hair loss
- Possibly fever, sensitivity to cold, shivering, gynecomastia, and lymphadenopathy

- Identification of the underlying cause

- Hospitalization, with protective isolation and hygienic measures to prevent secondary bacterial infection
- Open wet dressings, with colloidal baths
- Bland lotions over topical steroids
- Maintenance of constant environmental temperature to prevent chilling or overheating
- Careful monitoring of renal and cardiac status
- Systemic antibiotics and steroids
- Other nursing interventions similar to those for atopic dermatitis

Localized neurodermatitis (lichen simplex chronicus, essential pruritus)

Superficial skin inflammation characterized by itching and papular eruptions that appear on thickened, hyperpigmented skin

- Chronic scratching or rubbing of a primary lesion, insect bite, or other skin irritation

- Intense, sometimes continual scratching
- Thick, sharpbordered, possibly dry, scaly lesions, with raised papules
- Usually affects easily reached areas, such as ankles, lower legs, anogenital area, back of neck, and ears

- Physical findings

- Scratching must stop; then erosions will disappear in 2 weeks
- Fixed dressing or Unna's boot to cover affected area
- Topical steroids (occlusive dressings or intralesional injections)
- Antihistamines and open wet dressings
- Emollients

Nummular dermatitis

Chronic form of dermatitis characterized by coin-shaped, vesicular, crusted scales and, possibly, pruritic lesions

- Possibly precipitated by stress; or dryness, irritants, or scratching

- Round, nummular (coin-shaped) lesions, usually on arms and legs, with distinct borders of crusts and scales
- Possibly oozing and severe itching
- Summertime remissions common, with wintertime recurrence

- Physical findings and patient history; history of atopic dermatitis in middle-aged or older patient
- Exclusion of fungal infections, atopic or contact dermatitis, and psoriasis

- Elimination of known irritants
- Measures to relieve dry skin: increased humidification, limited frequency of baths and use of bland soap and bath oils, and application of emollients
- Wet dressings in acute phase
- Topical steroids (occlusive dressings or intralesional injections) for persistent lesions
- Tar preparations and antihistamines for itching and antibiotics for secondary infection

		recurrence	contact dermatitis, and psoriasis	dressings or intralesional injections) for persistent lesions <ul style="list-style-type: none">▫ Tar preparations and antihistamines for itching and antibiotics for secondary infection▫ Other interventions similar to those for atopic dermatitis
<hr/>				
Seborrheic dermatitis				
An acute or subacute disease that affects the scalp, face and, occasionally, other areas and is characterized by lesions covered with yellow or brownish gray scales	<ul style="list-style-type: none">▫ Unknown; stress and neurologic conditions may be predisposing factors	<ul style="list-style-type: none">▫ Eruptions in areas with many sebaceous glands (usually scalp, face, and trunk) and in skin folds▫ Itching, redness, and inflammation of affected areas; lesions that may appear greasy; possibly fissures▫ Indistinct, occasionally yellowish scaly patches from excess stratum corneum (dandruff may be a mild seborrheic dermatitis)	<ul style="list-style-type: none">▫ Patient history and physical findings, especially distribution of lesions in sebaceous gland areas▫ Exclusion of psoriasis	<ul style="list-style-type: none">▫ Removal of scales by frequent washing and shampooing with selenium sulfide suspension, zinc pyrithione, tar and salicylic acid shampoo or ketoconazole shampoo▫ Application of topical steroids and antifungal agents to nonhairy areas
<hr/>				
Stasis dermatitis				
Condition usually caused by impaired circulation and characterized by eczema of the legs with edema, hyperpigmentation, and persistent inflammation	<ul style="list-style-type: none">▫ Secondary to peripheral vascular diseases affecting legs, such as recurrent thrombophlebitis and resultant chronic venous insufficiency	<ul style="list-style-type: none">▫ Varicosities and edema common, but obvious vascular insufficiency not always present▫ Usually affects the lower leg, just above internal malleolus, or sites of trauma or irritation▫ Early signs: dusky red deposits of hemosiderin in skin, with itching and dimpling of subcutaneous tissue; later signs: edema, redness, and scaling of large area of legs▫ Possibly fissures, crusts, and ulcers	<ul style="list-style-type: none">▫ Positive history of venous insufficiency and physical findings such as varicosities	<ul style="list-style-type: none">▫ Measures to prevent venous stasis: avoidance of prolonged sitting or standing, use of support stockings, and weight reduction for obese patients▫ Corrective surgery for underlying cause▫ After ulcer develops, rest periods with legs elevated; open wet dressings; Unna's boot, (provides continuous pressure to areas); and antibiotics for secondary infection after wound culture

Serum analysis shows elevated IgE levels; tissue cultures may be done to rule out bacterial, viral, or fungal superinfections; and allergy testing may be done to identify allergic rhinitis or asthma.

Treatment

Effective treatment of atopic lesions consists of eliminating allergens and avoiding irritants, extreme temperature changes, and other precipitating factors. Local and systemic measures relieve itching and inflammation.

Systemic antihistamines, such as hydroxyzine hydrochloride and diphenhydramine, relieve pruritus, and topical application of a corticosteroid cream, especially after bathing, often alleviates inflammation. A typical medication routine may include a systemic antihistamine, a topical corticosteroid, and a bland emollient. Between steroid doses, application of petroleum jelly can help retain moisture.

Systemic corticosteroid therapy should be used only during extreme exacerbations. Weak tar preparations and ultraviolet B light therapy are used to increase the thickness of the stratum corneum. Antibiotics are appropriate if a bacterial agent has been cultured; antifungal or antiviral medications may be prescribed to fight a fungal or viral infection.

Nursing diagnoses

u Altered oral mucous membrane u Body image disturbance u Impaired skin integrity u Knowledge deficit u Pain u Risk for infection

Key outcomes

- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will report feelings of increased comfort.
- u The patient will avoid or minimize complications.
- u The patient and family members will demonstrate the skin care regimen.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Assist the patient in scheduling daily skin care. Keep his fingernails short to limit excoriation and secondary infections caused by scratching.
- u Be alert for possible adverse effects associated with corticosteroid use: sensitivity reactions, gastric disturbances, musculoskeletal weakness, neurologic disturbances, and cushingoid symptoms.
- u To help clear lichenified skin, apply occlusive dressings, such as a plastic film, intermittently. This treatment requires a doctor's order and experience in dermatologic treatment.
- u Apply cool, moist compresses to relieve itching and burning.
- u Encourage the patient to verbalize feelings about his appearance, including embarrassment and fear of rejection. Offer him emotional support and reassurance and arrange for counseling if necessary.

Patient teaching

- u Provide written instructions for skin care and treatment with corticosteroids. Teach the patient and family members to recognize signs of corticosteroid overdose and to notify the doctor immediately if they occur.
- u If the patient experiences an excessively dry mouth because of antihistamine use, advise him to drink water or suck ice chips.
- u Warn that drowsiness is possible with the use of antihistamines to relieve daytime itching. If nocturnal itching interferes with sleep, suggest methods for inducing natural sleep, such as drinking a glass of warm milk, to prevent overuse of sedatives.
- u Stress the importance of meticulous hand washing and good personal hygiene.
- u Caution the patient to avoid bathing in hot water because heat causes vasodilation, which induces pruritus.

- Instruct the patient to use plain, tepid water (96° F [35.6° C]) with a nonfatty, nonperfumed soap but to avoid using any soap when lesions are acutely inflamed. Advise him to shampoo frequently and to apply corticosteroid solution to the scalp afterward. Suggest using a lubricating lotion after a bath.
- In severe dermatitis, show the patient how to apply occlusive dressings. For example, hands with severe contact dermatitis may require a topical corticosteroid and occlusion with gloves to increase drug absorption and skin hydration.
- Teach the patient how to apply wet-to-dry dressings to soothe inflammation, itching, and burning; remove crusting and scales from dry lesions; and help dry up oozing lesions.
- Help the patient to identify and avoid aggravating factors and allergens associated with atopic dermatitis. Suggest that he investigate his daily life for possible irritants.

Miscellaneous disorders

Many other disorders can affect the skin. They range from potentially fatal disorders, such as epidermolysis bullosa, to common, benign disorders such as warts.

CORNS AND CALLUSES

Corns and calluses—usually located on areas of repeated trauma (most often the feet)—are acquired skin conditions. A corn is marked by hyperkeratosis of the stratum corneum and is classified as soft or hard. A callus is an area of thickened skin, generally on the foot or hand. People whose activities produce repeated trauma (for example, manual laborers or guitarists) commonly develop calluses. The severity of a corn or callus depends on the degree and duration of trauma. The prognosis for both is good with proper hand or foot care.

Causes

A corn usually results from external pressure, such as that from ill-fitting shoes or, less commonly, from internal pressure, such as that caused by a protruding underlying bone (resulting from arthritis, for example). A callus is produced by external pressure or friction.

Complications

Secondary infections may occur when patients try to cut away corns or calluses with sharp instruments.

Assessment findings

The patient may complain of pain when pressure is applied to the area. A thorough history discloses chronic friction or pressure.

On inspection, you're able to differentiate corns from calluses: Corns contain a central keratinous core, are smaller and more clearly defined than calluses, and are usually more painful. Soft corns appear as whitish thickenings and are commonly found between the toes, most often in the fourth interdigital web. Hard corns are sharply delineated and conical and appear most frequently over the dorsolateral aspect of the fifth toe. In contrast, if the patient has a callus, you'll note that the lesion, which may be quite large, has an indefinite border. Although calluses commonly appear over plantar warts, normal skin markings distinguish them from the warts.

Palpation of a corn may elicit a complaint of dull and constant, or even sharp, pain. Palpation of a callus usually produces dull pain on pressure rather than constant pain.

Diagnostic tests

No tests are needed because examination is reliable for identifying corns and calluses.

Treatment

Surgical debridement may be performed, usually under a local anesthetic, to remove the nucleus of a corn. In intermittent debridement, keratolytics—usually 40% salicylic acid plasters—are applied to affected areas. Injections of corticosteroids beneath the corn may be necessary to relieve pain. However, the simplest and best treatment is essentially preventive—avoidance of trauma. Corns and calluses disappear after the source of trauma has been removed. Metatarsal pads may redistribute the weight-bearing areas of the foot; corn pads may prevent painful pressure.

Patients with persistent corns or calluses require referral to a podiatrist or dermatologist; those with corns or calluses caused by a bony malformation, as in arthritis, require an orthopedic consultation.

Nursing diagnoses

- Impaired physical mobility
- Impaired skin integrity
- Knowledge deficit
- Pain

Key outcomes

- The patient will express feelings of comfort.
- The patient will maintain joint mobility and range of motion.
- The patient and family members will express an understanding of the disorder and treatment.
- The patient will avoid complications.

Nursing interventions

- Promote progressive mobilization to the maximum allowable within the patient's pain limitation.
- When applying salicylic acid plasters, make sure the plaster is large enough to cover the affected area. Place the sticky side against the patient's skin, and cover the plaster with adhesive tape.
- Watch for sensitivity reactions associated with salicylic acid plasters.

Patient teaching

- Teach the patient how to apply salicylic acid plasters. Tell him that the plasters are usually taken off after an overnight application but may be left in place for as long as 7 days. After removing the plaster, the patient should soak the area in water and abrade the soft, macerated skin with a towel or pumice stone. He should then reapply the plaster and repeat the entire procedure until he has removed all the hyperkeratotic skin.
- Warn the patient against removing corns or calluses with a sharp instrument such as a razor blade.
- Advise him to wear properly fitted shoes. Suggest the use of metatarsal or corn pads to relieve pressure. Refer him to a podiatrist, a dermatologist, or an orthopedist if necessary.
- Assure him that good foot care can correct these conditions.
- If the patient is to have his corns or calluses debrided, give preoperative and postoperative instructions.

EPIDERMOLYSIS BULLOSA

Epidermolysis bullosa is a heterogeneous group of disorders that affect the skin and mucous membranes and produces blisters in response to normally harmless heat

and frictional trauma. As many as 16 scarring and nonscarring forms may exist, including an acquired form (epidermolysis bullosa acquisita) that develops after childhood and isn't genetically inherited.

All nonscarring forms produce a split *above* the basement membrane, the layer between the epidermis and dermis. The scarring forms—except for dominant dystrophic epidermolysis bullosa—produce a split *below* the basement membrane in the upper part of the dermis. Children with dystrophic epidermolysis bullosa have been found to have fewer—and abnormal—anchoring fibrils securing the epidermis to the dermis. These children also have more—and abnormal—collagenase, an enzyme that may destroy the anchoring fibrils. Some patients with epidermolysis bullosa simplex also have deficiencies of other enzymes involved in collagen synthesis.

The prognosis depends on the severity of the disease. In the nonscarring forms of epidermolysis bullosa, the blisters become less severe and occur less frequently as the patient matures. The severe scarring forms commonly cause disability or disfigurement and may be fatal during infancy or childhood.

Causes

The nonscarring forms of epidermolysis bullosa result from autosomal dominant inheritance, except for junctional epidermolysis bullosa (epidermolysis bullosa Herlitz or epidermolysis bullosa letalis), which is recessively inherited.

Except for dominant dystrophic epidermolysis bullosa, the scarring forms result from autosomal recessive inheritance. Sometimes, this disorder occurs as a mutation in families with no history of blistering disorders.

Complications

In all scarring forms and some nonscarring forms, parturition causes widespread blistering and occasional sloughing of large areas of a neonate's skin. Neonates can develop sucking blisters as well as blistering in the GI, respiratory, or genitourinary tract that may lead to strictures or adhesions. Death may occur from fluid and electrolyte imbalance, heat loss, sepsis, and extensive scarring and mucocutaneous erosions.

Ocular complications may include eyelid blisters, conjunctivitis, blepharitis, adhesions, and corneal opacities. Other complications include fusion of fingers and toes with accompanying loss of function, delayed tooth eruption, malformed or carious teeth, alopecia, abnormal nails, retarded growth, anemia, constipation, malnutrition, infection, squamous cell carcinoma, and pyloric atresia.

Assessment findings

The patient history may reveal that tense, clear bullae first appeared in infancy, or they may not appear until early adulthood. Skin inspection may find lesions on any area exposed to friction, such as from footwear, crawling, and bed linens, or to warm weather. However, some forms of epidermolysis bullosa develop in areas not exposed to trauma. Common lesion sites include the feet, extensor surfaces of the extremities, and the knees and elbows.

If the patient has the simple form of epidermolysis bullosa, the lesions will be superficial; these usually heal without scarring. In the dystrophic form of the disease, you may see large eroded areas, hypertrophic scars, and adhesions on the upper dermis. On further inspection, you may note that the patient's fingers and toes have fused.

Differential diagnosis of epidermolysis bullosa should rule out other chronic, nonhereditary bullous diseases, such as juvenile bullous pemphigus, chronic bullous disease of childhood, and congenital herpes infection.

Diagnostic tests

Skin biopsy using immunofluorescence and electron microscopy of a freshly induced blister is used to identify the type of epidermolysis bullosa. Fetoscopy and biopsy at 20 weeks' gestation is used to identify the severe scarring forms. (Diagnosis can't be confirmed by amniocentesis alone.)

Treatment

Therapy is primarily supportive and preventive in nature. Phenytoin may be used to treat recessive dystrophic forms of epidermolysis bullosa; corticosteroids and retinoids may be used in other forms. Supportive treatment consists of guarding the skin from trauma and friction through application of protective dressings and skin lubricants. A high-calorie diet containing vitamin and mineral supplements helps combat chronic malnutrition, and iron supplements or transfusions help counteract anemia. Occupational and physical therapy help prevent contractures and deformities.

Nursing diagnoses

⌞ Altered oral mucous membrane ⌞ Body image disturbance ⌞ Fluid volume deficit ⌞ Impaired physical mobility ⌞ Impaired skin integrity ⌞ Impaired tissue integrity ⌞ Ineffective thermoregulation ⌞ Risk for infection

Key outcomes

- ⌞ The patient will express feelings of comfort.
- ⌞ The patient will exhibit improved or healed lesions or wounds.
- ⌞ The patient will remain free from signs and symptoms of infection.
- ⌞ The patient's fluid volume will remain within normal range.
- ⌞ The patient will voice feelings about his changed body image.

Nursing interventions

- ⌞ Use meticulous hand washing and hygiene to prevent secondary infection. Have the patient's fingernails cut short to minimize tissue trauma from scratching. Avoid friction from bed linens, dressings, and clothing. If necessary, maintain protective isolation.
- ⌞ Be alert for complications associated with the use of corticosteroids, retinoids, and antibiotics. Possible adverse effects include GI disturbances, neurologic dysfunction, musculoskeletal weakness, and cushingoid symptoms.
- ⌞ Inspect and assess the lesions on mucous membranes. Provide frequent mouth care, avoid astringent or acidic fluids, and provide the patient with a bland, soft diet to prevent infection and promote comfort.
- ⌞ If the patient is a critically ill infant, use an Isolette to maintain body temperature and provide isolation. Carefully monitor intake and output and laboratory test results to assess fluid and electrolyte balance. Maintain I.V. fluid replacement as necessary. Check vital signs, being especially alert for temperature spikes, which indicate sepsis.
- ⌞ Maintain the patient's skin integrity and promote circulation. Assess the extent of scarring and adhesions.
- ⌞ Preserve joint mobility and prevent contractures with passive and active range-of-motion (ROM) exercises. In severe cases, place the patient in a Stryker frame or CircOlectric bed and arrange for physical and occupational therapy.
- ⌞ Encourage the patient and family members to express their feelings. Discuss embarrassment, fear of rejection by others, loss of function, and the potential loss of the infant.
- ⌞ Refer the patient and family members to a mental health professional for additional counseling if necessary and to any local support groups.

Patient teaching

- ⌞ Emphasize the importance of meticulous hand washing, and teach the patient to use aseptic technique when changing dressings to prevent secondary infection.
- ⌞ Stress the importance of avoiding trauma and friction. Encourage the use of protective clothing, such as properly fitted shoes, nonrestrictive long-sleeved shirts and

- long pants, and knee pads for crawling infants.
- u Teach the patient and family members active and passive ROM exercises to minimize disability from scarring and joint immobility.
 - u Provide written instructions about the patient's diet and treatment regimen. Warn the patient and family members about possible adverse drug reactions and instruct them to notify the doctor if any occur.
 - u Help the patient to identify his strengths, and reinforce effective coping behaviors. Provide a realistic assessment of the patient's condition, and avoid giving false hope for a complete recovery.

PITYRIASIS ROSEA

Pityriasis rosea is an acute, self-limiting, inflammatory skin disease that produces a “herald” patch, which usually goes undetected, followed by a generalized eruption of papulosquamous lesions. Although this noncontagious disorder may develop at any age, it's most likely to occur in adolescents and young adults. The incidence increases in the spring and fall. Secondary syphilis, dermatophytosis, or a drug reaction may mimic the condition.

Causes

In pityriasis rosea, the cause is unknown, but the disease's brief course and the virtual absence of recurrence suggest a viral agent or an autoimmune disorder.

Complications

Pruritus and scratching may lead to secondary bacterial infections.

Assessment findings

The patient with pityriasis may initially complain of a slightly raised, oval, erythematous lesion anywhere on his body. (Although this lesion is ¼" to 2 ⅜" [2 to 6 cm] in diameter, many patients don't notice this herald patch.) After a few days to several weeks, the patient may note lesions on his trunk and extremities. Most patients report only slight itching; sometimes, however, the itching may be severe.

Inspection of the patient's skin may reveal red to brown patches with an erythematous border and trailing scales. The lesions are oval, ¼" to ⅜" (0.6 to 1 cm) in diameter, and arranged along body cleavage lines, producing a pattern similar to that of a pine tree. The patches may be macular, vesicular, or urticarial.

On further questioning, the patient may disclose that the eruptions have continued for 7 to 10 days. The patches may persist for 2 to 6 weeks.

Diagnostic tests

Serologic testing is used to rule out secondary syphilis.

Treatment

Focusing on relief of pruritus, treatment involves emollients, oatmeal baths, antihistamines and, occasionally, exposure to ultraviolet light or sunlight. Topical steroids in a hydrophilic cream base may be beneficial. Rarely, if inflammation is severe, systemic corticosteroids may be required.

Nursing diagnoses

- u Body image disturbance u Impaired skin integrity u Knowledge deficit u Risk for infection

Key outcomes

- u The patient will remain free from signs and symptoms of infection.
- u The patient will avoid complications.
- u The patient will verbalize an understanding of the condition and treatment regimen.
- u The patient will voice feelings about his changed body image.

Nursing interventions

- u Have the patient's fingernails cut short to prevent secondary bacterial infection from scratching.
- u Give antihistamines as ordered to relieve pruritus.
- u Encourage the patient to verbalize feelings about his appearance. Reassure him that pityriasis rosea is noncontagious, that spontaneous remission usually occurs in 2 to 6 weeks, and that lesions generally don't recur.

Patient teaching

- u Explain the disease and all procedures.
- u Provide written instructions for the treatment regimen. Make sure the patient understands his prescribed treatment and medication routine. Warn him that antihistamines may cause drowsiness.
- u Encourage good hand washing and personal hygiene. Advise the patient to avoid hot baths or showers, which intensify itching. Encourage him to use lubricating lotions after bathing.

PRESSURE ULCERS

Pressure ulcers are localized areas of cellular necrosis that occur most often in the skin and subcutaneous tissue over bony prominences, especially the sacrum, ischial tuberosities, greater trochanter, heels, malleoli, and elbows. These ulcers—also called decubitus ulcers, pressure sores, or bedsores—may be superficial, caused by local skin irritation with subsequent surface maceration, or deep, originating in underlying tissue. Deep lesions often go undetected until they penetrate the skin but, by then, they've usually caused subcutaneous damage.

Causes and pathophysiology

Pressure, particularly over bony prominences, interrupts normal circulatory function and causes most pressure ulcers. The intensity and duration of such pressure govern the severity of the ulcer; pressure exerted over an area for a moderate period (1 to 2 hours) produces tissue ischemia and increased capillary pressure, leading to edema and multiple small-vessel thromboses. An inflammatory reaction gives way to ulceration and necrosis of ischemic cells. In turn, necrotic tissue predisposes the body to bacterial invasion and infection. (See [Pressure points: Common sites of pressure ulcers.](#))

Shearing force, the force applied when tissue layers move over one another, can also cause ulcerations. This force stretches the skin, compressing local circulation. For example, if the head of the patient's bed is raised, gravity tends to pull the patient downward and forward, creating a shearing force. The friction of the patient's skin against the bed, such as occurs when a patient slides himself up in bed rather than lifting his hips, compounds the problem.

Moisture, whether from perspiration or incontinence, can also cause pressure ulcers. Such moisture softens skin layers and provides an environment for bacterial growth, leading to skin breakdown.

Other factors that can predispose a patient to pressure ulcers and also delay healing include poor nutrition, diabetes mellitus, paralysis, cardiovascular disorders, and aging. Added risks include obesity, insufficient weight, edema, anemia, poor hygiene, and exposure to chemicals.

Complications

Bacterial invasion and secondary infection, possibly leading to bacteremia and septicemia, are common complications of pressure ulcers. If the ulcer is large, a continuous loss of serum may deplete the body of its normal circulating fluids and essential proteins. In severe cases, ulcers may extend through subcutaneous fat layers, fibrous tissue, and muscle until reaching the bone.

Pressure points: Common sites of pressure ulcers

Pressure ulcers may develop at any of these pressure points. To prevent sores, reposition the patient and check carefully for any skin changes.

The diagram illustrates four common patient positions and the pressure points where ulcers are most likely to develop. In the sitting position (wheelchair), pressure points are the shoulder blades, sacrum, ischia tuberosity, posterior knee, and anus. In the sitting position (chair), the pressure point is the sacrum. In the supine position (on the back), pressure points are the occiput, heels of the feet, elbows, and the dorsal thoracic area. In the lateral position (on the side), pressure points are the side of the head, shoulder, trochanter, anterior knee, and malleolus.

Assessment findings

The patient with a pressure ulcer has a history of one or more predisposing factors. Inspection of an early, superficial lesion notes shiny, erythematous changes over the compressed area, caused by localized vasodilation when pressure is relieved. If the superficial erythema has progressed, you'll see small blisters or erosions and, ultimately, necrosis and ulceration.

In underlying damage from pressure between deep tissue and bone, you'll note an inflamed skin surface area. Bacteria in a compressed site cause inflammation and, eventually, infection, which leads to further necrosis. You may detect a foul-smelling, purulent discharge seeping from a lesion that has penetrated the skin from beneath. A black eschar may develop around and over the lesion because infected, necrotic tissue prevents healthy granulation of scar tissue. (See [Four stages of pressure ulcers](#).)

Four stages of pressure ulcers

To protect the patient from pressure ulcer complications, learn to recognize the four stages of ulcer formation.

Stage 1

In this stage, the skin stays red for 5 minutes after removal of pressure and may develop an abrasion of the epidermis. (A black person's skin may look purple.) The skin also feels warm and firm. The sore is usually reversible if you remove pressure.

Stage 2

Breaks appear in the skin, and discoloration may occur. Penetrating to the subcutaneous fat layer, the sore is painful and visibly swollen. If pressure is removed, the sore may heal within 1 to 2 weeks.

Stage 3

A hole develops that oozes foul-smelling yellow or green fluid. The ulcer extends into the muscle and may develop a black leathery crust or eschar at its edges and, eventually, at the center. The ulcer isn't painful, but healing may take months.

Stage 4

The ulcer destroys tissue from the skin to the bone and becomes necrotic. Findings include foul drainage and deep tunnels that extend from the ulcer. Months or even a year may elapse before the ulcer heals.

Diagnostic tests

Wound culture and sensitivity testing of the ulcer exudate are used to identify infecting organisms. Serum protein and serum albumin studies may be ordered to

determine severe hypoproteinemia.

ADVANCED PRACTICE

Aids for preventing and treating pressure ulcers

Aids for preventing and treating pressure ulcers include relief devices and topical agents.

Pressure relief aids

- u *Gel flotation pads* disperse pressure over a greater skin surface area and are convenient and adaptable for home and wheelchair use.
- u *Alternating pressure mattresses* contain tubelike sections, running lengthwise that deflate and reinflate, changing areas of pressure. Use the mattress with a single untucked sheet because layers of linen decrease its effectiveness.
- u *Convolutd foam mattresses* minimize area of skin pressure with their alternating areas of depression and elevation; soft, elevated foam areas cushion skin and depressed areas relieve pressure. This mattress should be used with a single, loosely tucked sheet and is adaptable for home and wheelchair use. If the patient is incontinent, cover the mattress with the provided plastic sleeve.
- u *Spanco mattresses* have polyester fibers with silicon tubes to decrease pressure without limiting the patient's position. It has no weight limitation.
- u *Clinitron beds* support the patient at a subcapillary pressure point and provide a warm, relaxing therapeutic airflow. The bed is filled with beads that move when the air flows. It eliminates friction and maceration.
- u *Low-air-loss beds*, such as Flexicare and Accucare, slow the drying of any saline soaks, and elderly patients often experience less disorientation than with high-air-loss beds. The head of the bed can be elevated so there is less chance of aspiration, especially in patients who require tube feeding. Patients can get out of bed more easily and can be moved more easily on low-air-loss surfaces.

Topical agents

- u Gentle soap
- u Dakin's solution
- u Zinc oxide cream
- u Absorbable gelatin sponge
- u Dextranomer (inert, absorbing beads)
- u Karaya gum patches
- u Topical antibiotics (*only* when infection is confirmed by culture and sensitivity tests)
- u Silver sulfadiazine cream (antimicrobial agent) for necrotic areas
- u Water vapor—permeable dressings
- u DuoDerm, Tegaderm dressings

Skin-damaging agents to avoid

- u Harsh alkali soaps
- u Alcohol-based products (may cause vasoconstriction)
- u Tincture of benzoin (may cause vasoconstriction)
- u Hexachlorophene (may irritate the central nervous system)
- u Petroleum gauze

Treatment

Prevention is most important in pressure ulcers, by such means as movement and exercise to improve circulation and adequate nutrition to maintain skin health. When pressure ulcers do develop, successful management involves relieving pressure on the affected area, keeping the area clean and dry, and promoting healing. To relieve pressure, devices such as pads, mattresses, and special beds may be used. Turning and repositioning are still necessary. (See [Aids for preventing and treating pressure ulcers](#).) In addition, a diet high in protein, iron, and vitamin C helps to promote healing.

Other treatments depend on the ulcer stage. Stage 1 treatment aims to increase tissue pliability, stimulate local circulation, promote healing, and prevent skin breakdown. Specific measures include the use of lubricants (such as Lubriderm), clear plastic dressings (Op-Site), gelatin-type wafers (DuoDerm), vasodilator sprays (Proderm), and whirlpool baths.

For stage 2 ulcers, additional treatments include cleaning the ulcer with normal saline solution. This removes ulcer debris and helps prevent further skin damage and infection.

Therapy for stage 3 or 4 ulcers aims to treat existing infection, prevent further infection, and remove necrotic tissue. Specific measures include cleaning the ulcer with povidone-iodine solution and applying granular and absorbent dressings. These dressings promote wound drainage and absorb any exudate. In addition, enzymatic ointments (such as Elase or Travase) break down dead tissue, whereas healing ointments clean deep or infected ulcers and stimulate new cell growth.

Debridement of necrotic tissue may be necessary to allow healing. One method is to apply open wet dressings and allow them to dry on the ulcer. Removal of the dressings mechanically debrides exudate and necrotic tissue. On occasion, the ulcer may require debridement using surgical, mechanical, or chemical techniques. In severe cases, skin grafting may be necessary.

Nursing diagnoses

- u Altered nutrition: Less than body requirements
- u Altered protection
- u Impaired physical mobility
- u Impaired skin integrity
- u Impaired tissue integrity
- u Risk for infection

Key outcomes

- u The patient will exhibit improved or healed lesions or wounds.
- u The patient will maintain adequate daily calorie intake.
- u The patient will maintain joint mobility and range of motion (ROM).
- u The patient will remain free from signs and symptoms of infection.
- u The patient will avoid complications.

Nursing interventions

- u During each shift, check the bedridden patient's skin for changes in color, turgor, temperature, and sensation. Examine an existing ulcer for any change in size or degree of damage.
- u Reposition the bedridden patient at least every 2 hours around the clock. Minimize the effects of shearing force by using a footboard and not raising the head of the bed to an angle that exceeds 60 degrees. Keep the patient's knees slightly flexed for short periods.
- u Perform passive ROM exercises or encourage the patient to do active exercises if possible.

- u To prevent pressure ulcers in an immobilized patient, use pressure-relief aids on the bed.
- u Give the patient meticulous skin care. Keep the skin clean and dry without using harsh soaps. Gently massaging the skin around the affected area (not on it) promotes healing. Rub moisturizing lotions into the skin thoroughly to prevent maceration of the skin surface. Change bed linens frequently for a diaphoretic or incontinent patient.
- u If the patient is incontinent, offer a bedpan or commode frequently. Use only a single layer of padding for urine and fecal incontinence because excessive padding increases perspiration, which leads to maceration. Excessive padding may also wrinkle, irritating the skin.
- u Clean open lesions with normal saline solution. If possible, expose the lesions to air and sunlight to promote healing. Dressings, if needed, should be porous and lightly taped to healthy skin.
- u Encourage adequate food and fluid intake to maintain body weight and promote healing. Consult the dietitian to provide a diet that promotes granulation of new tissue. Encourage the debilitated patient to eat frequent, small meals that include protein- and calorie-rich supplements. Assist the weakened patient with meals.
- u Because anemia and elevated blood glucose levels may lead to skin breakdown, monitor hemoglobin and blood glucose levels and hematocrit.

Patient teaching

- u Explain the function of pressure-relief aids and topical agents and demonstrate their proper use.
- u Teach the patient and family members position-changing techniques and active and passive ROM exercises.
- u Stress good hygiene. Teach the patient to avoid skin-damaging agents, such as harsh soaps, alcohol-based products, tincture of benzoin, and hexachlorophene.
- u As indicated, explain debridement procedures and prepare the patient for skin graft surgery.
- u Teach the patient and family members to recognize and record signs of healing. Explain that treatment typically varies according to the stage of healing.
- u Encourage the patient to eat a well-balanced diet and consume an adequate amount of fluids, explaining their importance for skin health. Point out dietary sources rich in vitamin C, which aids wound healing, promotes iron absorption, and helps in collagen formation.

PSORIASIS

Psoriasis is a chronic skin disease marked by epidermal proliferation and characterized by recurring remissions and exacerbations. Its lesions, which appear as erythematous papules and plaques covered with silvery scales, vary widely in severity and distribution.

Psoriasis affects about 2% of the U.S. population, and the incidence is higher among whites than among people of other races. The disease affects men and women equally and, although it may occur at any age, it occurs less frequently after age 40.

Flare-ups are often related to specific systemic and environmental factors but may be unpredictable; they can usually be controlled with therapy.

Causes and pathophysiology

The tendency to develop psoriasis is genetically determined. Researchers have discovered a significantly higher than normal incidence of certain histocompatibility antigens (HLAs) in patients with psoriasis, suggesting a possible autoimmune process.

The onset of the disease is also influenced by environmental factors. Trauma can trigger the isomorphic effect, or Koebner's phenomenon, in which lesions develop at injury sites. Infections, especially those resulting from beta-hemolytic streptococci, may cause a flare of guttate (drop-shaped) lesions. Other contributing factors include pregnancy, endocrine changes, climatic conditions (cold weather tends to exacerbate psoriasis), and emotional stress.

A skin cell normally takes 14 days to move from the basal layer to the stratum corneum where, after 14 days of normal wear and tear, it's sloughed off. In contrast to this 28-day cycle, the life cycle of a psoriatic cell is only 4 days. This markedly shortened cycle doesn't allow time for the cell to mature. Consequently, the stratum corneum becomes thick and flaky, producing the cardinal manifestations of psoriasis.

Complications

If the patient doesn't comply with prescribed treatment, infection may result. Also, altered self-image may lead to social isolation and depression.

Assessment findings

The patient history may reveal a family history of psoriasis as well as predisposing factors. The patient complains of skin lesions that itch and burn and may be painful. He may also describe arthritic symptoms— “morning stiffness”—usually in one or more finger or toe joints, sometimes in the sacroiliac joints. In some patients, this progresses to spondylitis. Joint symptoms show no consistent linkage to the course of the cutaneous manifestation of psoriasis; they demonstrate remissions and exacerbations similar to those of rheumatoid arthritis.

On inspection, you see erythematous, well-defined plaques covered with characteristic silver scales. In mild psoriasis, plaques are scattered over a small skin area. The patient with moderate psoriasis displays more and larger plaques, up to several centimeters in diameter. Severe psoriasis involves at least half the body.

ADVANCED PRACTICE

Identifying types of psoriasis

Psoriasis occurs in various forms, ranging from one or two localized plaques that seldom require long-term medical attention to widespread lesions and crippling arthritis.

Erythrodermic psoriasis

This type is marked by extensive flushing all over the body, which may or may not result in scaling. The rash may begin rapidly, signaling new psoriasis; it may develop gradually in chronic psoriasis; or it may occur as an adverse reaction to a drug.

Guttate psoriasis

This type typically affects children and young adults. Erupting in drop-sized plaques over the trunk, arms, legs and, sometimes, the scalp, this rash of plaques generalizes in several days. It's commonly associated with upper respiratory tract streptococcal infections.

Inverse psoriasis

Smooth, dry, bright red plaques characterize inverse psoriasis. Located in skin folds (the armpits and groin, for example), the plaques fissure easily.

Psoriasis vulgaris

This is the most common type of psoriasis. It begins with red, dotlike lesions that gradually enlarge and produce dry, silvery scales. The plaques usually appear symmetrically on the knees, elbows, extremities, genitalia, scalp, and nails.

Pustular psoriasis

This type features an eruption of local or extensive small, raised, pus-filled plaques. Precursors include emotional stress, sweat, infections, and adverse drug reactions.

Plaques usually appear on the scalp, chest, elbows, knees, back, and buttocks. Palpation may cause the scales to flake off easily, or you may note that the scales have thickened and covered the lesion. Attempting to remove the psoriatic scales may produce fine bleeding points (Auspitz sign). You may also see small guttate lesions, either alone or with plaques; these lesions are typically thin and erythematous, with few scales. (See [Identifying types of psoriasis.](#))

In about 30% of patients, psoriasis has spread to the fingernails or, more often, the toenails, producing small indentations or pits and yellow or brown discoloration. In severe cases, the accumulation of thick, crumbly debris under the nail causes the nail to separate from the nail bed.

Diagnostic tests

The patient history and appearance of lesions guide the diagnosis. A skin biopsy helps to rule out other diseases. The serum uric acid level is elevated because of accelerated nucleic acid degradation, but indications of gout are absent. HLA-Cw6, B-13, and Bw-57 may be present in early-onset familial psoriasis.

Treatment

Treatment depends on the type of psoriasis, extent of the disease, and effect of the disease on the patient's life. No permanent cure exists; all treatments are palliative.

Lukewarm baths and the application of occlusive ointment bases, such as petroleum jelly, or preparations that contain urea or salicylic acid may soften and help remove psoriatic scales. Steroid creams are also useful.

Methods to retard rapid cell production include exposure to ultraviolet B (UVB) light or natural sunlight to the point of minimal erythema. Coal tar preparations retard skin cell growth and relieve inflammation, itching, and scaling.

Topical corticosteroids are the treatment of choice for mild to moderate psoriasis of the trunk, arms, and legs. These drugs decrease epidermal cell growth and reduce inflammation. They may also reduce symptoms by inducing vasoconstriction. Treatment commonly combines topical corticosteroids with emollients, coal tar preparations, and UV light therapy. For many patients, this is an inexpensive regimen that minimizes adverse effects. Topical vitamin D has shown to be as effective as topical steroids.

Mild psoriasis involving the extremities may be relieved by 0.025% triamcinolone acetonide ointment. Facial, groin, or axillary plaques may respond to 1% desonide cream or alclometasone dipropionate. More potent topical preparations, such as 0.1% betamethasone valerate or 0.1% triamcinolone acetonide, may be prescribed for moderate psoriasis.

Anthralin may help large plaques that don't respond to coal tar or topical corticosteroid preparations. Methotrexate, a drug that inhibits cell replication, may relieve severe, unresponsive psoriasis. Acitretin is a potent retinoic acid derivative that may be used for psoriasis that is resistant to other drugs or treatments. It's especially effective for treating pustular and erythrodermic psoriasis and may also relieve extensive plaque-type psoriasis. However, the disease commonly recurs within 2 months after the cessation of therapy.

Patients with severe chronic psoriasis may use the Goeckerman treatment, which combines topical coal tar treatment with ultraviolet A (UVA) or UVB light therapy. The regimen is used monthly during flare-ups; it may also be used to treat chronic, resistant plaques for extended periods. The Ingram technique is a variation of this treatment, using anthralin instead of coal tar. A modified Goeckerman treatment combines UVB light therapy with topical drugs, such as coal tar preparations, corticosteroids, or kerolytic agents. This therapy may relieve psoriasis more quickly than the standard Goeckerman treatment, but remission may be briefer. A photochemotherapy program called PUVA combines administration of psoralen, either orally or topically, with exposure to UVA light. Cyclosporine (Neoral), an immunosuppressant, is used for severe widespread psoriasis and results in dramatic clearing.

Low-dose antihistamine therapy, oatmeal baths, emollients (perhaps with phenol and menthol), and open wet dressings may help relieve pruritus. Aspirin and local heat help alleviate the pain of psoriatic arthritis; severe cases may require nonsteroidal anti-inflammatory drugs.

Therapy for patients with psoriasis of the scalp typically consists of a coal tar shampoo, followed by the application of a steroid lotion while the hair is still wet. No effective treatment exists for psoriasis of the nails. The nails usually improve as skin lesions improve.

Nursing diagnoses

u Body image disturbance u Impaired skin integrity u Knowledge deficit u Pain u Powerlessness u Social isolation

Key outcomes

u The patient will exhibit improved or healed lesions or wounds.
u The patient will report feelings of increased comfort.

- u The patient will avoid or minimize complications.
- u The patient will voice feelings about his changed body image.
- u The patient and family members will demonstrate the skin care regimen.
- u The patient and family members will express an understanding of the condition and treatment.

Nursing interventions

- u Carefully monitor for adverse reactions to therapy.
- u Ensure proper patient teaching, and offer sympathetic support.
- u Apply all topical medications, especially those that contain anthralin and coal tar, with a downward motion to avoid rubbing them into the follicles. Wear gloves because anthralin stains and injures the skin. After application, allow the patient to dust himself with powder to help prevent anthralin from rubbing off on his clothes.
- u Watch for adverse reactions to therapeutic agents. These may include allergic reactions to anthralin; atrophy and acne from steroids; and burning, itching, nausea, and squamous cell epitheliomas from PUVA.
- u Initially evaluate the patient on methotrexate weekly and then monthly for red blood cell, white blood cell, and platelet counts because cytotoxins may cause hepatic or bone marrow toxicity. Liver biopsy may be done to assess the effects of methotrexate.
- u Monitor triglycerides, cholesterol, and liver function tests for acitretin. Patients on cyclosporine need renal function and blood pressure monitoring.
- u Encourage the patient to verbalize feelings about his appearance; feelings of embarrassment, frustration, or powerlessness; or fear of rejection. Involve family members in the treatment regimen to reduce the patient's feelings of social isolation. Help the patient build a positive self-image by encouraging his participation in activities that deemphasize appearance.

Patient teaching

- u Explain the causes, predisposing factors, and course of psoriasis to the patient and family members. Stress that psoriasis isn't communicable. Advise them that exacerbations and remissions commonly occur but that they can usually control the disorder by adhering to the treatment regimen.
- u Make sure the patient understands his prescribed therapy; provide written instructions to avoid confusion. Teach correct application of prescribed ointments, creams, and lotions.
- u Instruct the patient to avoid scratching the plaques. Suggest that he wear gloves to help protect the skin from unconscious scratching. Tell him that pressing ice cubes against the lesions or applying a mentholated shaving cream may provide relief. Recommend using a humidifier in the winter to avoid dry skin, which may increase itching.
- u Caution the patient to avoid scrubbing his skin vigorously. If a medication has been applied to the scales to soften them, suggest that the patient use a soft brush to remove them.
- u Warn the patient never to put an occlusive dressing over anthralin. Suggest the use of mineral oil and then soap and water to remove anthralin.
- u Caution the patient receiving PUVA therapy to stay out of the sun on the treatment day and to protect his eyes with sunglasses that screen UVA for 24 hours after treatment. Tell him to wear goggles during exposure to this light.
- u If the patient is using acitretin, inform him that the drug may remain in his body for up to 3 years after the treatment ends. For this reason, discourage female patients who may want to become pregnant from using this drug.
- u Caution the patient using methotrexate not to drink alcoholic beverages; explain that alcohol ingestion increases the risk of hepatotoxicity.
- u Warn the patient and family members about possible adverse effects associated with the therapeutic agents; tell them to notify the doctor if any occur.
- u Teach the patient stress-reduction techniques and injury prevention strategies to prevent exacerbations.
- u Explain the relation between psoriasis and arthritis, but point out that psoriasis causes no other systemic disturbances.
- u Refer the patient to the National Psoriasis Foundation.

WARTS

Warts (also called verrucae) are common, benign infections of the skin and adjacent mucous membranes. Although warts may occur at any age, common warts (verrucae vulgaris) are most prevalent in children and young adults. Flat warts usually occur in children but can also affect adults. Genital warts may be transmitted through sexual contact; however, they're not always venereal in origin.

The prognosis varies: Some warts disappear readily with treatment; others necessitate vigorous, prolonged treatment. About 8% to 10% of the population have warts.

Causes

Warts are caused by infection with the human papillomavirus, a group of ether-resistant, deoxyribonucleic acid-containing papovaviruses. The mode of transmission is probably through direct contact, but autoinoculation is possible.

Complications

Common complications include secondary infection and scarring.

Assessment findings

- Clinical signs depend on the type of wart:
- u *Common*. This wart is usually found on the extremities, particularly the hands and fingers. Inspection and palpation reveal rough, elevated, rounded surfaces.
 - u *Filliform*. Inspection exposes a single, thin, threadlike projection, commonly around the face and neck.
 - u *Periungual*. Inspection of the patient's fingernails and toenails discloses rough, irregularly shaped, elevated surfaces around the nail edges. If the wart has extended under the nail and lifted it off the nail bed, the patient may complain of pain.
 - u *Flat*. Inspection and palpation reveal multiple groupings of up to several hundred slightly raised lesions with smooth, flat, or slightly rounded tops. You may notice the lesions on the patient's face, neck, chest, knees, legs, dorsa of the hands, wrists, and flexor surfaces of the forearms. The distribution is often linear because these warts can spread from scratching or shaving.
 - u *Plantar*. The patient may complain of pain in his feet with pressure. Inspection of the pressure points of the patient's feet finds slightly elevated or flat lesions appearing singly or in large clusters (mosaic warts). The warts may obliterate the natural skin lines.
 - u *Digitate*. Inspection of the scalp and hairline shows a fingerlike, horny projection, arising from a pea-shaped base.
 - u *Moist*. Inspection of the penis, scrotum, vulva, or anus reveals small pink to red warts, known also as condyloma acuminatum. Moist and soft, the warts may appear singly or in large cauliflower-like clusters.

Diagnostic tests

Visual examination usually confirms the diagnosis. Recurrent anal warts require sigmoidoscopy to rule out internal involvement, which may necessitate surgery. To distinguish plantar warts from corns and calluses, gently shave down the lesion with a scalpel; plantar warts exhibit red or black capillary dots.

Treatment

Effective treatment varies with the location, size, and number of warts. It also depends on the patient's age, pain level (current and projected), history of therapy, and compliance with treatment. Most people develop an immune response that causes warts to disappear spontaneously and require no treatment.

- Treatment may include:
- u *electrodesiccation and curettage*. High-frequency electric current destroys the wart and is followed by surgical removal of dead tissue at the base. After application of an antibiotic ointment, the area is covered with a bandage for 48 hours.
 - u *cryotherapy*. Liquid nitrogen kills the wart; the resulting dried blister is peeled off several days later. If initial treatment isn't successful, it can be repeated at 2- to 4-week intervals. This method is useful for either periungual warts or for common warts on the face, extremities, penis, vagina, or anus.

u *acid therapy (primary or adjunctive)*. The patient applies acid-impregnated plaster patches (such as 40% salicylic acid plasters) or acid drops (such as 5% to 20% salicylic and lactic acid in flexible collodion [Duofilm]) every 12 to 24 hours for 2 to 4 weeks. This method isn't recommended for areas in which perspiration is heavy or that are likely to get wet or for exposed body parts on which patches are cosmetically undesirable.

u *25% podophyllum resin in compound with tincture of benzoin (for venereal warts)*. The podophyllum solution is applied on moist warts. The patient must lie still while it dries, leave it on for 4 hours, and then wash it off with soap and water. The treatment may be repeated every 3 to 4 days and, in some cases, must be left on a maximum of 24 hours, depending on the patient's tolerance. The use of this drug is contraindicated in pregnant patients.

The use of antiviral drugs is under investigation. Suggestion and hypnosis are occasionally successful, especially with children. Carbon dioxide laser treatment has successfully been used to remove all types of warts.

Nursing diagnoses

u Body image disturbance u Impaired skin integrity u Pain u Risk for infection

Key outcomes

u The patient will exhibit improved or healed lesions or wounds.

u The patient will report feelings of increased comfort.

u The patient will avoid or minimize complications.

u The patient will voice feelings about his changed body image.

Nursing interventions

u To protect adjacent unaffected skin during acid or podophyllum treatment, cover it with petroleum jelly or sodium bicarbonate.

u Encourage the patient to verbalize feelings about his appearance. Discuss any embarrassment or fear of reaction he may have. Offer emotional support, and assure him that warts respond to treatment.

u Be alert for possible adverse effects of acid therapy, such as burning and irritation of surrounding tissues.

Patient teaching

u Teach the patient and family members that warts are contagious and can be spread by shaving, sharing personal articles, scratching, and sexual contact. Help the patient to identify all contacts, and tell him that he should encourage them to seek medical treatment. Advise him that warts commonly recur.

u If the patient is receiving acid therapy, make sure he knows how to apply the plaster patches. Instruct him to leave the patches on for 12 to 24 hours. Stress the importance of protecting healthy tissue and avoiding picking, rubbing, or scratching lesions. Emphasize that compliance with the treatment regimen is essential for successful wart removal and to prevent scarring.

u If the patient is receiving electrosurgery to remove warts, explain the procedure and give any preoperative and postoperative instructions.

APPENDIX: NUTRITIONAL DISORDERS

This appendix provides a summary of nutritional disorders. It briefly describes each disorder's characteristics, possible causes, signs and symptoms, and treatment.

Hypervitaminosis is a condition that results from the accumulation of excessive amounts of one or more vitamins. This accumulation occurs because the vitamins aren't dissolved and then excreted in urine. These conditions are most prevalent in infants and children and commonly result from accidental or misguided overdose of supplemental vitamin preparations. In chronic hypervitaminosis A, signs and symptoms include anorexia, irritability, headache, hair loss, malaise, itching, vertigo, and bone pain. In hypervitaminosis D, anorexia, headache, nausea, vomiting, weight loss, polyuria, and polydipsia occur. Withholding vitamin supplements usually corrects hypervitaminoses A and D.

Iodine deficiency is the lack of sufficient levels of iodine to satisfy daily metabolic requirements. This deficiency may lead to hypothyroidism and thyroid hypertrophy (endemic goiter). Other effects range from dental caries to cretinism in infants born to mothers with iodine deficiency. Insufficient ingestion of dietary iodine or increased metabolic demands during pregnancy, lactation, and adolescence may cause this deficit. Signs and symptoms vary. Treatment consists of iodine supplements.

Obesity is a body weight that exceeds the norm by 20% or more. This condition results when calorie intake consistently exceeds metabolic demands. Theories to explain this condition include psychological factors, hypothalamic dysfunction of hunger and satiety centers, genetic predisposition, abnormal absorption of nutrients, and impaired action of GI and growth hormones and of hormonal regulators such as insulin. An inverse relationship between socioeconomic status and the prevalence of obesity has been documented, especially in women. Obesity in parents increases the probability of obesity in children. Weight reduction and maintenance of proper weight are the goals of treatment, which includes a low-calorie diet, behavior modification, aerobic exercise, and social support.

Protein-calorie malnutrition refers to one of two conditions: marasmus (an inadequate intake of both calories and protein) or kwashiorkor (a protein deficiency, despite sufficient intake of calories). Both disorders commonly affect infants in underdeveloped countries. In industrialized countries, these disorders most commonly affect hospitalized patients. Infants with marasmus suffer from growth retardation and wasting, physical inactivity, apathy, frequent infections, anorexia, weakness, irritability, hunger, diarrhea, nausea, and vomiting. In kwashiorkor, the child may be severely lethargic, irritable, and anorexic. Growth retardation may be less pronounced than in marasmus. Treatment involves providing high-quality protein foods and protein-calorie supplements.

Vitamin A deficiency, or decreased serum levels of vitamin A, commonly results from inadequate dietary intake of foods high in vitamin A, which maintains epithelial tissue and retinal function. Other causes include malabsorption, massive urinary excretion caused by other disorders, and decreased storage and transport of vitamin A in hepatic disease. Night blindness and mild conjunctival changes may be reversed with oral or parenteral doses of vitamin A. Dry and scaly skin responds to cream or petroleum jelly—based products. Corneal damage requires emergency treatment.

Vitamin B deficiencies are characterized by low urine or serum levels of B-complex vitamins, water-soluble vitamins essential to normal metabolism, cell growth, and blood formation.

Thiamine (B_1) deficiency results from malabsorption or inadequate dietary intake of thiamine. Early complaints include anorexia, irritability, muscle cramps, and paresthesia. Advanced deficiency may result in complaints related to heart disease or the nervous system.

Riboflavin (B_2) deficiency results from a diet deficient in milk; meat; fish; green, leafy vegetables; and legumes. Signs and symptoms include sore throat and mouth, weakness, and eye involvement (such as burning, itching, light sensitivity, and tearing).

Niacin deficiency predominantly affects those who subsist mainly on corn and consume minimal animal protein. It's also associated with alcoholism and nutrient-drug interactions. Early-stage complaints include fatigue, anorexia, muscle weakness, headache, indigestion, weight loss, and backache. Advanced deficiency (pellagra) may produce skin eruptions, mouth soreness, GI distress, and dementia.

Pyridoxine (B_6) deficiency, which is uncommon in adults, usually occurs from pyridoxine destruction by autoclaving infant formulas. Signs and symptoms include sore mouth, weakness, abdominal pain, irritability, dermatitis, vomiting, and central nervous system disturbances.

Cobalamin (B_{12}) deficiency, causing anorexia, weight loss, abdominal discomfort, sore mouth, diarrhea, and constipation, commonly results from an absence of intrinsic factor in gastric secretions or an absence of receptor sites after ileal resection.

Diet and supplementary vitamins can prevent or correct vitamin B deficiencies.

Vitamin C deficiency, or insufficient serum levels of ascorbic acid (vitamin C), is primarily caused by a diet lacking foods rich in vitamin C. The deficiency is characterized by weakness, malaise, anorexia, limb and joint pain, and capillary fragility. Advanced deficiency can lead to scurvy, bone fractures, and psychological disturbances. Signs and symptoms subside in a few days to 3 weeks with adequate vitamin C intake.

Vitamin D deficiency is a nutritional deficit that interferes with normal bone calcification, resulting in rickets in infants and young children and osteomalacia in adults. Rare today, this deficiency results from inadequate dietary intake of preformed vitamin D, malabsorption of vitamin D, or too little exposure to sunlight. Early signs and symptoms include profuse sweating, restlessness, and irritability. If bone deformity occurs, patients may have difficulty walking and climbing stairs, leg and lower back pain, bowed legs, knock-knees, poorly developed muscles, and infantile tetany. For osteomalacia and rickets—except when due to malabsorption—treatment consists of massive oral doses of vitamin D or cod liver oil. Rickets refractory to vitamin D or accompanied by hepatic or renal disease requires 25-hydroxycholecalciferol, 1,25-dihydroxycholecalciferol, or a synthetic analogue of active vitamin D.

Vitamin E deficiency manifests as hemolytic anemia in low-birth-weight or premature infants. In infants, this deficiency commonly results from formulas high in polyunsaturated fatty acids that are fortified with iron but not vitamin E. It also develops in conditions associated with fat malabsorption. Signs and symptoms include edema and skin lesions; adults may display muscle weakness, intermittent claudication, and gait disturbances. Replacement of vitamin E with a supplement is the only appropriate treatment.

Vitamin K deficiency is a deficiency of the element necessary for the formation of prothrombin and other clotting factors. This deficiency is common in neonates in the first few days postpartum because of poor placental transfer of vitamin K and inadequate production of vitamin K-producing intestinal flora. Other causes include prolonged use of certain drugs, decreased bile flow to the small intestine, malabsorption of vitamin K, chronic hepatic disease, and cystic fibrosis. The cardinal sign is an abnormal bleeding tendency. Treatment consists of administration of vitamin K with continued monitoring of prothrombin time to guide therapy.

Zinc deficiency is characterized by low serum levels of zinc, an essential trace element present in the bones, teeth, hair, skin, testes, liver, and muscles. This deficiency usually results from excessive intake of foods that bind zinc to form insoluble chelates, which prevent its absorption. Other causes include malabsorption disorders and malnutrition. Typically, the patient exhibits sparse hair growth; soft, misshapen nails; and dry, scaling skin. Treatment consists of correcting the underlying cause and administering supplements.
